Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

DERMATOLOGIC SURGERY

Preface

Credits for Figures

I. FUNDAMENTALS

1. Surgical Anatomy, Surface Anatomy, and Cosmetic Subunits
2. Wound Healing and Surgical Wound Dressings
3. Preoperative Evaluation, Patient Preparation, and Informed Consent
4. The Surgical Suite
5. Surgical Instrument Selection
6. Suture Materials and Needles
7. Antibiotics: Preoperative and Postoperative Considerations
8. Photography and Digital Technology in Dermatologic Surgery
9. Ethics in Dermatologic Surgery
10. Billing and Financial Considerations in Dermatologic Surgery
11. Clinical Research in Dermatologic Surgery

II. SURGICAL PROCEDURES FOR DIAGNOSIS, THERAPY, AND RECONSTRUCTION

12. Local Anesthesia, Regional Nerve Blocks, and Postoperative Pain Management
13. Suturing Techniques
14. Superficial Biopsy Techniques

15. Cryosurgery
16. Electrosurgery and Hemostasis
17. Incision and Drainage
18. Layered Excisions and Surgical Repairs
19. Dog-Ear Correction
20. Principles of Flap Dynamics
21. Advancement Flaps
22. Rotation Flaps
23. Transposition Flaps
24. Bilobed Flaps
25. Island Pedicle Flaps
26. Interpolation Flaps
27. Z-Plasty
28. Skin, Cartilage, and Composite Grafts
29. Mohs Micrographic Surgery
30. Advanced Techniques and Special Stains in Mohs Micrographic Surgery
31. Mohs and Staged Geometric Excision for Lentigo Maligna
32. Histopathology for Mohs Micrographic Surgery
33. Laboratory Techniques for Mohs Micrographic Surgery
34. Nail Surgery
35. Surgical Scar Revision
36. Managing Surgical Complications
37. Superficial Radiation Therapy and Electronic Brachytherapy

III. REGIONAL APPROACHES TO RECONSTRUCTION

38. Reconstruction of the Eyelids
39. Reconstruction of the Nose
40. Reconstruction of the Lips
41. Reconstruction of the Ears
42. Reconstruction of the Cheeks
43. Reconstruction of the Forehead
44. Reconstruction of the Scalp
45. Reconstruction of the Hands and Feet

IV. SURGICAL APPROACHES BY DISEASE STATE

- 46. Melanoma
- 47. Dysplastic Nevi
- 48. Nonmelanoma Skin Cancer
- 49. Keloids
- 50. Cysts
- 51. Acne
- 52. Vitiligo
- 53. Chronic Wounds
- 54. Hidradenitis Suppurativa

V. COSMETIC DERMATOLOGIC SURGERY

- 55. The Cosmetic Consultation
- 56. Dermabrasion
- 57. Neuromodulators
- 58. Fillers and Injectable Implants
- 59. Ethnic and Gender Considerations in the Use of Facial Fillers
- 60. Liposuction
- 61. Fat Transfer
- 62. Hair Transplantation
- 63. Lasers for Burns and Trauma
- 64. Lasers for Vascular Lesions
- 65. Lasers for Pigmented Lesions and Tattoos
- 66. Laser- and Light-Based Approaches to Hair Removal
- 67. Laser Resurfacing
- 68. Body-Contouring Devices and Noninvasive Fat Removal
- 69. Laser- and Light-Based Approaches to Hair Loss
- 70. Photodynamic Therapy for Acne, Actinic Keratoses, and Nonmelanoma Skin Cancer
- 71. Laser- and Light-Based Treatments in Skin of Color
- 72. Sclerotherapy and Management of Varicose Veins
- 73. Blepharoplasty
- 74. Facelift

VI. MANAGEMENT OF COSMETIC CONDITIONS

- 75. Approaches to Facial Wrinkles and Contouring
- 76. Approaches to Dyspigmentation
- 77. Approaches to Erythema and Telangiectasias
- 78. Approaches to Facial Rejuvenation
- 79. Approaches to Neck Rejuvenation
- 80. Approaches to Hand Rejuvenation
- 81. Approaches to Female Genital Rejuvenation

Chapter Number: Title	Video Number: Title
12. Local Anesthesia, Regional Nerve Blocks, and Postoperative Pain Management	Video 12-1: Traditional Microbotox
	Video 12-2: Aquagold Microbotox
	Video 12-3: Cryoanesthesia Utilization
	Video 12-4: Ring Block
	Video 12-5: Tetracaine Administration
	Video 12-6: Local Anesthesia of the Lower Eyelid
	Video 12-7: Local Anesthesia of the Upper Eyelid
	Video 12-8: Tumescence Anesthesia
	Video 12-9: Supraorbital/Supratrochlear Nerve Block
	Video 12-10: Infraorbital Nerve Block
	Video 12-11: External Nasal Nerve Block
	Video 12-12: Mental Nerve Block
	Video 12-13: Digital Nerve Block
13. Suturing Techniques	Video 13-1: Buried Vertical Mattress Suture
	Video 13-2: Set-Back Dermal Suture
	Video 13-3: Buried Horizontal Mattress Suture
	Video 13-4: Buried Purse-String Suture
	Video 13-5: Simple Interrupted Suture
	Video 13-6: Vertical Mattress Suture
	Video 13-7: Horizontal Mattress
	Video 13-8: Tip Stitch
	Video 13-9: Purse-String Suture
	Video 13-10: Fascial Plication Suture
16. Electrosurgery and Hemostasis	Video 16-1: Electrocautery
	Video 16-2: Bipolar Electrocautery
	Video 16-3: Electrodesiccation and Curettage
17. Incision and Drainage	Video 17-1: Incision and Drainage
18. Layered Excision and Surgical Repairs	Video 18-1: Excision and Layered Closure
	Video 18-2: Excision and Layered Closure
	Video 18-3: Excision and Layered Closure
	Video 18-4: Excision and Layered Closure
	Video 18-5: Excision and Layered Closure
	Video 18-6: Excision and Layered Closure
	Video 18-7: Excision and Layered Closure
	Video 18-8: Excision and Layered Closure
	Video 18-9: Excision and Layered Closure
	Video 18-10: Excision and Layered Closure
21. Advancement Flaps	Video 21-1: Helical Rim/Chondrocutaneous Advancement Flap
	Video 21-2: Advancement Flap (O to L) on the Upper Cutaneous Lip
	Video 21-3: Advancement Flap (O to U) on the Upper Eyelid

24. Bilobed Flaps	Video 24-1: The Bilobed Flap
	Video 24-2: Dermabrasion After Bilobed Flap Repair
26. Interpolation Flaps	Video 26-1: Paramedian Forehead Flap (Nasal Tip Subunit)
	Video 26-2: Paramedian Forehead Flap (Ala)
28. Skin, Cartilage, and Composite Grafts	Video 28-1: Full-Thickness Skin Graft (FTSG)
	Video 28-2: Split-Thickness Skin Graft (STSG)
	Video 28-3: Cartilage Graft and FTSG
	Video 28-4: Weck Blade Harvest of STSG
29. Mohs Micrographic Surgery	Video 29-1: Mohs Surgery Technique: Tissue Excision
31. Mohs and Staged Geometric Excision for Lentigo Maligna	Video 31-1: Inking Template
	Video 31-2: Transfer Template
	Video 31-3: Inscribe 2 mm Margin
	Video 31-4: Sampling Negative Control
	Video 31-5: Suturing Negative Control
	Video 31-6: Removing Lentigo Maligna
	Video 31-7: Undermining
	Video 31-8: Plication and Intradermal Suture
	Video 31-9: Defatting and Thinning
	Video 31-10: Quadrisecting
	Video 31-11: Inking Quadrants
	Video 31-12: Mounting Pie Wedges
	Video 31-13: Mounting Radial Sections
	Video 31-14: Grossing-In
	Video 31-15: Mounting Specimens on Chuck
	Video 31-16: Quadrisecting
33. Laboratory Techniques for Mohs Micrographic Surgery	Video 31-17: Radial Sections
	Video 31-18: Defatting
	Video 31-19: Quadrisecting
	Video 31-20: Cutting Pie Wedges
	Video 33-1: Mohs Surgery: Tissue Processing
34. Nail Surgery	Video 34-1: Distal Digital Block
	Video 34-2: Application of Tourniquet
	Video 34-3: Tangential Shave Removal of Matrix Pigmented Lesion
	Video 34-4: Matrix Cauterization 1
	Video 34-5: Matrix Cauterization 2
	Video 34-6: Matrix Cauterization 3
	Video 34-7: Matrix Cauterization 4
	Video 34-8: Matrix Cauterization 5
38. Reconstruction of the Eyelids	Video 38-1: Diagonal Superior Suture Placement
	Video 38-2: Inverse Tenzel flap
	Video 38-3: Island Pedicle Flap with Canthal Suspension
	Video 38-4: Lateral Canthopexy

46. Melanoma	Video 46-1: Interrupted Deep Dermal Suture Placement for Wide Excision and Closure
	Video 46-2: Running Subcuticular Suture Placement for Wide Excision and Closure
	Video 46-3: Gamma Probe Detection of Radioactive Sentinel Lymph Node
	Video 46-4: Dissection and Excision of Sentinel Node Using Bipolar Electrocautery
	Video 46-5: Incision with Scalpel for Complete Groin Dissection
48. Nonmelanoma Skin Cancer	Video 48-1: Excision of Nonmelanoma Skin Cancer
50. Cysts	Video 50-1: Cyst Surgery Slit Excision
	Video 50-2: Using Punch Biopsy Tool to Remove Epidermoid Cyst
	Video 50-3: Milia Extraction
	Video 50-4: Pilar Cyst Excision
	Video 50-5: Marking Surgical Area and Applying Tegaderm Prior to Local Anesthesia
52. Vitiligo	Video 52-1: Donor Site Preparation
	Video 52-2: Donor Site Anesthesia
	Video 52-3: Harvesting the Graft
	Video 52-4: Bandaging the Donor Site
	Video 52-5: Recipient Site Preparation, Part 1
	Video 52-6: Recipient Site Preparation, Part 2
	Video 52-7: Applying Cell Suspension and Bandaging the Recipient Site
	Video 52-8: Cell Separation: 1: Rinsing the Graft
	Video 52-9: Cell Separation: 2: Flattening the Graft
	Video 52-10: Cell Separation: 3: Incubating the Graft
	Video 52-11: Cell Separation: 4: Removal of Trypsin
	Video 52-12: Cell Separation: 5: Rinsing the Trypsin from the Graft
	Video 52-13: Cell Separation: 6: Removal of the Dermis
	Video 52-14: Cell Separation: 7: Scraping the Graft
53. Chronic Wounds	Video 52-15: Cell Separation: 8: Transferring the Graft Fragments
	Video 52-16: Cell Separation: 9: Centrifugation of the Graft Fragments
	Video 52-17: Cell Separation: 10: Formation of the Cell Pellet
	Video 52-18: Cell Separation: 11: Removal of Tissue Fragments
	Video 52-19: Cell Separation: 12: Isolation of the Cell Pellet
	Video 52-20: Cell Separation: 13: Resuspending the Cell Pellet
	Video 52-21: Cell Separation: 14: Drawing up the Cell Suspension
	Video 53-1: Apligraf Placement
	Video 53-2: Debridement
	Video 53-3: Porcine Small Intestine Submucosa
	Video 53-4: Unna Boot Placement

54. Hidradenitis Suppurativa	Video 54-1: Intralesional Triamcinolone
	Video 54-2: Incision and Drainage
	Video 54-3: Deroofing
	Video 54-4: Limited Excision: Axilla
	Video 54-5: Limited Excision: Groin
	Video 54-6: CO ₂ Laser
	Video 54-7: Probing the Floor
	Video 54-8: Wide Excision
57. Neuromodulators	Video 57-1: Reconstitution of Botox
	Video 57-2: Demonstration of Glabellar Injection
	Video 57-3: Demonstration of Lateral Canthal Line Injection
	Video 57-4: Demonstration of Bunny Line Injection
	Video 57-5: Demonstration of Masseter Injection
	Video 57-6: Demonstration of Depressor Anguli Oris Injection
58. Fillers and Injectable Implants	Video 58-1: Facial Vascular Anatomy
	Video 58-2: Temple Marking
	Video 58-3: Temple Treatment
	Video 58-4: Midface Marking
	Video 58-5: Midface Treatment
	Video 58-6: Lower Face Treatment
	Video 58-7: Piriform Fossae Perioral Treatment
	Video 58-8: Lip Treatment
59. Ethnic and Gender Considerations in the Use of Facial Fillers	Video 59-1: Ethnic and Gender-Specific Approaches to Fillers
60. Liposuction	Video 60-1: Water-Assisted Tumescent Spray
	Video 60-2: VASER Ultrasound Technology Demonstrated Through a Scar Revision
	Video 60-3: Superficial Etching of the Abdominal Lines
	Video 60-4: Internal Radiofrequency (ThermiRF) Demonstrated After Liposuction of the Arms
	Video 60-5: Superficial Etching of the Abdominal Lines Using Hand Extraction
	Video 60-6: Purified Fat Injections to the Buttock Using a Single Port in the Buttock Fold
62. Hair Transplantation	Video 62-1: Hair Transplant
65. Lasers for Pigmented Lesions and Tattoos	Video 65-1: Tattoo Removal 755-nm Laser
	Video 65-2: Hand Lentiginos Treatment
66. Laser- and Light-Based Approaches to Hair Removal	Video 66-1: Laser Hair Removal with a Diode Laser
	Video 66-2: Laser Hair Removal with an Nd:YAG Laser
67. Laser Resurfacing	Video 67-1: Fractional Carbon Dioxide Laser Resurfacing of Photodamaged Skin
	Video 67-2: Fractional Er: YAG Laser Resurfacing of Photodamaged Skin
	Video 67-3: Fractional RF Resurfacing of Acne Scars
72. Sclerotherapy and Management of Varicose Veins	Video 72-1: Liquid Sclerotherapy of Small Varicosities
	Video 72-2: Foam Sclerotherapy

73. Blepharoplasty	Video 73-1: Upper and Lower Lid Blepharoplasty
74. Facelift	Video 74-1: Weekend Facelift, Part 1 Video 74-2: Weekend Facelift, Part 2 Video 74-3: Weekend Facelift, Part 3
75. Approaches to Facial Wrinkles and Contouring	Video 75-1: Forehead and Eyebrow Tissue Augmentation and BTX-A to Forehead Video 75-2: Infrabrow Hollow Tissue Augmentation Video 75-3: Upper Face Botulinum Toxin Video 75-4: Temple Tissue Augmentation Video 75-5: Zygoma Augmentation Video 75-6: Tear Trough Tissue Augmentation Video 75-7: Masseters/Facial Slimming with Botulinum Toxin Video 75-8: Upper Medial Cheek Tissue Augmentation Video 75-9: Submalar Cheek Tissue Augmentation Video 75-10: Nasal Tissue Augmentation and Bunny Line BTX-A Video 75-11: Chin Augmentation Along with BTX-A to Mentalis Muscle
80. Approaches to Hand Rejuvenation	Video 80-1: Calcium Hydroxyapatite Injection: Dorsal Hand Video 80-2: Compression Sclerotherapy: Dorsal Hand
81. Approaches to Female Genital Rejuvenation	Video 81-1: Marking the Wedge Video 81-2: Labiaplasty Wedge Video 81-3: Fat Grafting

Preface

Dermatologic surgery is a young field. During the past four decades, dermatology has pivoted from a primarily medical specialty to an organ-based medical and surgical subspecialty.

Dermatologic surgeons in the United States now not only perform more surgical excisions and linear repairs for skin cancer than all other specialists combined, but the majority of local flaps and grafts as well. At the same time, dermatologic surgeons have wholeheartedly embraced an evidence-based approach to surgical care, and the dramatic expansion in everything from clinical trials to survey studies during the past few decades has been astonishing.

Similarly, aesthetic dermatology has undergone an expansionist trend, with studies suggesting that dermatologists are increasingly seen as the experts of choice for cosmetic procedures.

There are many outstanding dermatologic surgery textbooks both in and out of print, and ideally the reader—whether a budding dermatologic surgeon or a wizened expert—should pore over as many of these as possible.

One of the goals for this text was to produce a book that, at least in rough measure, would reflect the proportion of time, effort, and training required for any given subject. Thus, for example, no fewer than five full chapters (in addition to numerous other sections) are dedicated to Mohs surgery. Similarly, a total of 17 richly illustrated chapters, including those devoted to particular flap techniques and regional approaches to reconstruction, address flap and graft closures, because exposure to a breadth of approaches may be transformative in allowing the trainee to develop a surgical eye. Since anatomy is the foundation on which all surgery is built, the anatomy chapter is centered on a true ground-up cadaveric study of head and neck anatomy with an eye to clinical relevance.

Dermatologic Surgery is, therefore, a bridge text, with the benefits of a single-volume multiauthor global dermatologic surgery textbook coupled with the strengths of a dedicated flap and reconstructive text. It includes not only flap chapters but reconstructive chapters for specific anatomic locations as well. This combination provides both fundamental flap technique didactics and a regional reconstructive approach, which cements the breadth of reconstructive options available to the dermatologic surgeon.

Diversity in dermatology is important, not only for surgeons, but for patients as well. Thus, this text includes a chapter focused on ethnic and gender differences in filler use, a chapter on laser use in skin of color, and a detailed chapter on the burgeoning field of female genital rejuvenation. The world of dermatologic surgery is changing rapidly, and therefore chapters on ethics, billing and financial considerations, clinical research, radiation therapy, body contouring, and others have been included. Cosmetic dermatologic surgery is a rapidly evolving field; therefore, this text takes a real-world approach to the use of fillers and neuromodulators, since the majority of their use in dermatologic surgery is outside of the narrow confines of FDA-approved indications.

By devoting special sections to surgical treatments by disease state for everything from melanoma and dysplastic nevi to hidradenitis and vitiligo, both a forward- and backward-referencing capability are added. Similarly, for cosmetic treatments, the book includes chapters that are centered not only on a given treatment (vascular lasers, dermabrasion, or fillers) but also by condition or concern, so that the reader can learn approaches both from the ground up and in a natural didactic fashion based on the patient's presenting concerns.

Full-length high-quality videos are an essential adjunct to learning procedural techniques, and this text is accompanied by the largest video resource of its kind ever compiled. This resource, coupled with close to 3,000 high-quality clinical photographs and nearly 500 professional medical illustrations, including infographics with surgical pearls for each chapter—with many pearls stratified by beginner tips, expert tips, cautions, patient education points, and even billing tips—help make this text truly unique.

Finally, this text is the first of its kind to include a chapter dedicated solely to laser treatment for burns and trauma. This chapter should serve as a resource and inspiration for clinicians eager to help those who may stand to benefit the most from some of the techniques discussed throughout this book.

I am honored to have an all-star cast of section editors who helped with recruiting chapter authors. These section editors include prominent academic and private-practice dermatologic surgeons who, among other honors, have served as president of the American Board of Dermatology, president of the American College of Mohs Surgery (two of the section editors), president of the American Society for Dermatologic Surgery, and editor in chief of the *Dermatologic Surgery* journal.

CHAPTER 1 Surgical Anatomy, Surface Anatomy, and Cosmetic Subunits

Nirusha Lachman
Wojciech Pawlina
Basel Sharaf
Kevin N. Christensen

SUMMARY

- Conceptualizing superficial anatomy as a three-dimensional-layered system helps understand the course and location of important neurovascular structures as they travel in a stepwise pattern in and between the muscular, bony and fascial planes to reach their terminal areas of supply and innervation.
- When approaching anatomically susceptible regions (“danger zones”), understanding the depth, course, and relation of these structures as they traverse anatomical boundaries provides the key to successful surgery.

Beginner Pearls

- Striated muscles of the face (muscles of facial expression) produce movement of the overlying soft tissue by creating tension transmitted by fibrous strands (retinacula) that connect the SMAS to the skin.
- Facial nerve branches, while generally protected by the SMAS, are surgically vulnerable as they reach areas of transition along their course toward their final destination.
- The forehead and temple are functionally related to the scalp, and through SMAS can easily glide over the skull.

Expert Pearls

- The internal carotid artery via its ophthalmic branch supplies a central triangular area including the eyes, superior nose, and central portion of the forehead.
- The angular artery and vein cross the medial canthal tendon and contribute to an important site of anastomosis just superior to the tendon between branches of the external carotid (facial artery) and internal carotid (ophthalmic artery).
- Nasal blood supply is mainly from the angular artery externally and the sphenopalatine artery internally, with smaller contributions from the superior labial and ophthalmic arteries.
- The parotid gland is contained within a shiny, tight fascial sheath (the parotid fascia), which helps differentiate it from fat.

Don't Forget!

- The key area of anastomosis between the external and internal carotid arteries is located above the medial canthal tendon where the angular artery communicates with the dorsal nasal branch of the ophthalmic artery.
- Both the facial artery and the marginal branch of the facial nerve lie deep to the fibers of the platysma.

Pitfalls and Cautions

- Erb's point, located 6 cm below the midpoint of a line connecting the angle of the mandible with the mastoid process, provides a landmark for the exit point of the superficial cervical nerves and the accessory nerve (cranial nerve XI).
- The mandibular branch of the facial nerve crosses over the facial artery about 5 to 10 mm above the point at which the facial artery crosses the mandible.

CHAPTER 1 Surgical Anatomy, Surface Anatomy, and Cosmetic Subunits

INTRODUCTION

Successful surgical reconstruction of the skin and soft tissues involves an understanding of the architecture of the superficial face and how to maintain its natural anatomy following surgical manipulation. Anatomically, the superficial face displays significant variation in skin thickness, texture, color, subcutaneous fat, and laxity.

Naturally occurring lines divide the face into demarcated areas referred to as cosmetic units. As these cosmetic units tend to display anatomical homogeneity, surgical repair for ideal cosmetic outcome should be based on preservation of the subunits by maintaining incision lines along or within natural contour lines. Cosmetic units are demarcated by contour lines that divide the face anteriorly into the (1) forehead, (2) nose, (3) cheeks, (4) eyes, and (5) lip. Anterolaterally, contour lines bound the (6) cheeks and laterally the (7) ears. Each of these areas is then divided into subunits.

The description of the anatomy is based on visualization of structures as they travel from one anatomical plane to another along their course and distribution. It is important to keep in perspective the changing relationships that exist between the fascial, superficial, and deep muscle layers and the important traversing neurovascular structures. As these relationships are mostly predictable, a thorough understanding of the underlying anatomy within the operative field limits hesitation and improves surgical confidence.

KEY PRINCIPLES FOR UNDERSTANDING FACIAL ANATOMY

Relaxed skin tension lines of the face

Striated muscles of the face (muscles of facial expression) produce the movement of the overlying soft tissue by creating tension transmitted by fibrous strands (retinacula) that connect the superficial musculoaponeurotic system (SMAS) to the skin. In younger individuals, this tension is opposed by elastic fibers within the skin. With progressive aging, however, changes in the configuration of collagen fibers and the decreased ability of the elastic fibers to resist this tension result in the formation of wrinkle lines along these retinacula attachments. Relaxed skin tension lines (RSTLs), therefore, run perpendicular to the underlying muscle fibers; for example, wrinkle lines on the forehead run horizontally since the frontalis muscle contracts vertically.

Understanding the profiles of RSTLs is a key element in surgical planning with the goal of minimizing visible scarring. Techniques for scar reduction have been well described in the literature, and one principle is to align the long axis of the repair within or as close as possible to the RSTL to promote merging of the scar into the wrinkle line. While RSTLs are typically more pronounced and easily identifiable in elderly patients, the application of the anatomical arrangement of the underlying muscle fibers and its directional relationship to the fibrous septa is helpful in accentuating RSTLs when not easily identifiable. Therefore, having patients perform exaggerated facial expressions will expose these lines, while gentle manipulation of the skin may also highlight RSTLs (Fig. 1-1).

Figure 1-1. Diagram illustrating cosmetic subunit boundaries and relaxed skin tension lines.

UNDERSTANDING THE FASCIAL PLANES OF THE FACE AND NECK

The anatomy of the face and its subunits presents itself through a distinct arrangement of fascial planes that enclose subcutaneous tissue, superficial muscles, nerves, and blood vessels. Deconstructing the complex relationships that exist between these planes provides a view of the course and relations of vascular networks and important traversing branches of the superficial motor and sensory nerves. Understanding and predicting the trajectory of the branches of an intricate plexus of motor and sensory nerves within the muscular architecture is crucial to minimizing complications associated with dermatologic surgery.

A few basic concepts are strategic to predicting potential challenges that accompany surgical manipulation of the superficial face:

1. The face can be dissected through principle fascial planes that consist of skin, subcutaneous fibroadipose layer, SMAS, space containing traversing nerves and retaining ligaments, and deep fascial layer (Fig. 1-2).^{1,2}

Figure 1-2. Conceptual illustration demonstrating layers of the face from superficial to deep. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved).

2. Muscles of facial expression are not set within the same architectural plane. They are attached to the dermis and are reinforced by retaining

ligaments while maintaining an arrangement within a stepped configuration (Fig. 1-3).²

Figure 1-3. Diagram illustrating stepped configuration and arrangement of muscles of facial expression (mimetic muscles).

3. Exiting branches of the facial nerve are the principal motor suppliers of the muscles of facial expression and they tend to innervate these muscles through their deep surfaces, overlying muscles only as they traverse from their points of origin to innervation (Fig. 1-4).^{3,4}

Figure 1-4. Diagram illustrating standard pattern of distribution of branches of the facial nerve.

4. Facial nerve branches exit the parotid fascia along its anterior margin, often networking as they travel from a deep to superficial plane, while still lying deep to the SMAS plane (Fig. 1-5).⁵

Figure 1-5. Deep dissection of facial nerve with reflected upper portion of parotid gland.

5. Facial nerve branches divide into a variable number of rami, and in the mid-lateral face form a plexus of interconnected communications including connections between the facial nerve and the trigeminal nerve branches (Fig. 1-6).^{5,6}

Figure 1-6. Dissection of facial nerve deep to SMAS.

6. While the SMAS splits to enclose muscles of facial expression, it remains continuous with fascia of the platysma, superficial parotid fascia, galea aponeurotica, and superficial temporal fascia (temporoparietal fascia) (Fig. 1-2).⁷
7. While the superficial temporal vessels are contained within the SMAS, the sub-SMAS plane remains relatively avascular (Fig. 1-7).⁷

Figure 1-7. Conceptual illustration demonstrating relationship of structures within layers of the face from superficial to deep. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved).

8. Trigeminal nerve branches travel in a plane above the SMAS and then exit the supraorbital, infraorbital, and mental foramina, and travel in a deep to superficial direction toward the skin, where they lie within the subcutaneous fibro-adipose layer (Fig. 1-8).^{4,8-10}

Figure 1-8. Diagram illustrating distribution patterns of sensory branches of the trigeminal nerve.

9. The facial artery and its branches travel deep to the SMAS and run along a superficial course to cross palpable bony boundaries or penetrate the SMAS (Fig. 1-7).^{11,12}
10. The thickness of the subcutaneous layer varies significantly and displays fat compartments that are predictable and distinct within cosmetic subunits. The layer is more uniform in thickness over the scalp, while compaction of the subcutaneous tissue around the eyelids and lips appears to make this layer almost nonexistent.^{1,2,13,14}

Concept of the superficial musculoaponeurotic system

The concept of the SMAS is best understood by looking at the SMAS as a single continuous layer of organized fibrous network that divides at predictable locations in order to enclose the muscles of facial expression and keep them connected to the dermis.

Histologically, SMAS is described as a three-dimensional (3D) architecture of collagen, elastic fibers, adipose, and muscle tissue.^{2,4,7,15} Typically, the arrangement of SMAS determines the flexibility of the overlying structures. For example, SMAS can exhibit a meshwork of fibrous septa that envelops lobules of fat within an interconnecting fibrous network¹⁵ connected to facial muscles or periosteum. This type of arrangement is best demonstrated in the forehead; parotid, zygomatic, infraorbital regions; and lateral nasolabial fold.¹⁵

Alternately, in and around the upper and lower lip regions, SMAS exhibits an intermingling arrangement of collagen, muscles, and elastic fibers extending up to the dermis. Around these areas, single adipocytes, rather than adipose tissue accumulations (compartments), are interposed between the fibers. These regions represent highly innervated areas where numerous sensory nerve branches may be encountered during microscopic visualization.⁷

With regard to SMAS and its relationship with deeper investing fascia, two important points can be made about the fascia associated with temporalis muscle and the fascia associated with the masseter muscle. (1) As the temporalis muscle arises from the superior temporal line and the floor of the temporal fossa, it fans out to pass medially to the zygomatic arch and inserts onto the coronoid process and anterior border of the ramus of the mandible.¹⁶⁻¹⁸ A dense layer of deep fascia overlies the superficial surface of the muscle and is referred to as the *deep temporal fascia* which extends superiorly to attach to the superior temporal line. Deep temporal fascia is overlapped by the auricularis muscle anteriorly and superiorly by the epicranial aponeurosis and part of orbicularis oculi muscle.^{4,9}

In a region above the zygomatic arch, on the lateral aspect of the head, fascia continuous with the SMAS is separated from the temporal fascia by a layer of loose connective tissue with some adipose tissue and is commonly referred to as the *superficial temporal* or *temporoparietal fascia*. Within its two layers, the temporoparietal fascia^{11,16,19} contains the superficial temporal vessels,¹⁷ auriculotemporal nerve, and temporal branches of the facial nerve en route to the frontalis and portions of the orbicularis oculi muscles (Figs. 1-2 and 1-7).

(2) The deep fascia of the masseter muscle is intimately connected to the deep layer of the parotid capsule. As the deep investing fascia divides to

enclose the parotid gland, it is connected to the masseteric fascia and is often seen as a composite parotid–masseteric fascia.^{4,9} This close association between the fascial layers is mostly unyielding and does not provide easy access to a surgical plane. The superficial layer of the parotid fascia is continuous once again with the SMAS.

Topographic framework of the superficial face

The five-layer construct typically associated with the scalp can be applied in understanding the fascial framework of the face.² Most superficially, the first layer is the skin, with its epidermis and underlying dermis (Layer 1) varying in thickness, density, and regional conformation.² The subcutaneous plane (Layer 2) contains volume-defining adipose tissue and a fibrous “retinacular cutis” which is composed of dense irregular connective tissue characterized by thick, irregular bundles of mostly type I collagen and elastic fibers.²⁰ The reticular layer contains portions of retaining ligaments that traverse through the subcutaneous tissue (varying regional density) connecting the dermis to the SMAS.^{1,7}

The SMAS layer (Layer 3) is continuous over the entire face. The muscles of facial expression are contained within the composite superficial fascia (Layers 1–3) and lie within this layer, followed by deeper set muscles providing more functional roles (e.g., orbicularis oculi, orbicularis oris).^{7,15,16,21} Layer 3 reflects the galea aponeurotica of the scalp, superficial temporal fascia over the temporal region, orbicularis fascia in the orbital area, SMAS over the inferior face (mid and lower), and the platysma in the neck.¹⁵

Layer 4 consists of soft tissue spaces, facial ligaments, deep portions of the muscles of facial expression, and segments of the facial nerve branches traversing toward points of innervation.^{1,2} On the lateral face, anterior to the ear and extending down toward the posterior border of platysma, the superficial fascia fuses with the deep fascia (fibrous capsule of parotid gland), creating a tightly bound composite of Layers 1 to 5 thereby reducing Layer 4 to an undissectable plane (Fig. 1-2).²

Layer 5 is formed by the deep fascia overlying the superficial muscles of mastication (deep temporal fascia, masseteric fascia), by the periosteum

covering the bone, and the parotid fascia forming the unyielding fibrous capsule of the parotid gland (Figs. 1-2 and 1-7).^{1,2,9,15}

Surgically relevant anatomy within cosmetic units

In addition to Salasche et al.'s²² detailed and insightful account of the anatomy related to the surgery of the skin, recent research has added to the understanding of key anatomical concepts regarding dermatologic surgery within cosmetic units.^{23,24} The ensuing discussion of relevant anatomy has been built on the anatomy encountered during superficial dissection within these territories along with well-established reviews and current literature.

Forehead

- Muscles acting on the forehead and eyebrow: frontalis, corrugator supercilii, and procerus.
- The forehead and temple are functionally related to the scalp and through SMAS can easily glide over the skull.
- The supraorbital and supratrochlear neurovascular bundles supply this region.

The forehead extends from the hairline to the eyebrows in a vertical direction and ends laterally at the temporal ridges. Skin of the forehead varies in dermal thickness, decreasing as it extends superiorly toward the hairline. Additionally, while more taut in younger individuals, the skin of the forehead in older patients tends to be more mobile, usually as a result of chronological or actinic damage. Beneath the skin, the subcutaneous layer is minimal, usually not more than about 1 mm thick. Just deep to the subcutaneous tissue, the SMAS encloses the frontal or anterior belly of the occipitofrontalis muscle with its vertically oriented fibers. As the thickness of the muscle tends to decrease with age, these fibers can be rather sparse in older patients, making the traversing neurovascular structures easier to reach.

Between the left and right anterior bellies of occipitofrontalis, a fascial extension known as the galeal median raphe is present. The galeal raphe is devoid of muscle fibers and does not usually contain any significant

associated neurovascular structures. Inferiorly, superolateral fibers of the orbicularis oculi can be visualized as they interface with the medially located fibers of procerus and corrugator supercilii.

It is helpful to remember that the frontalis muscle is enveloped by superficial and deep investing layer of the SMAS and periosteum. The supratrochlear and supraorbital nerves are important structures that provide sensory innervation to the scalp and skin. They exit the supraorbital foramen within a neurovascular bundle above the orbital rim (Fig. 1-9). Christensen et al.²⁵ described the origin and depth of the supraorbital nerve. The neurovascular bundle originates an average of 26 mm from the midline and is 7.5 mm deep at its origin beneath the corrugator supercilii muscle, continuing superficially above frontalis muscle.

Figure 1-9. Anterior view of dissection of the upper face highlighting supratrochlear and supraorbital nerves.

The forehead receives vascular supply centrally from the right and left supratrochlear and supraorbital arteries and bilaterally by the anterior branch of the temporal arteries. These vessels are located in the subcutaneous tissue and are predictable in their location. The supratrochlear artery serves as the basis of the axial paramedian forehead flap (Fig. 1-10), and therefore knowing that the origin of the neurovascular bundle is approximately 13 mm

from the midline, in line with the medial canthus, may be helpful. Furthermore, the neurovascular bundle originates above the brow from the supraorbital foramen and is initially deep to the corrugator supercilii and above the periosteum. The bundle courses through the corrugator supercilii, initially deep to the frontalis, but as they move superiorly they branch and become more superficial, piercing the SMAS and coursing through the frontalis to reach the subcutaneous tissue (Fig. 1-11). Details of arterial diameter, depth, and branching patterns of the superficial temporal artery have been extensively described,²⁶ averaging 2 mm in diameter at a depth of 1 to 2 mm and with an average of nine visible branches. Rich collateral circulation of the forehead skin supports the use of random pattern cutaneous flaps.

Figure 1-10. Anatomy of anastomosis around the medial canthus of the left eye.

Figure 1-11. Supraorbital and supratrochlear nerves coursing over fibers of frontalis muscle.

Temple

- The superficial temporal artery travels within the layers of the superficial temporal fascia.
- Rich anastomosis occurs between branches of the superficial temporal artery and supraorbital artery.
- The auriculotemporal nerve runs deep and posterior to the superficial temporal artery.
- The frontal branch of the facial nerve is most vulnerable as it crosses the zygomatic arch as a single trunk en route to the deep surfaces of the frontalis muscle.

The temporal fossa contains a relatively sparse amount of subcutaneous tissue devoid of muscles of facial expression, with the exception of traversing fibers of the orbicularis oculi muscle and even fewer fibers of the anterior auricular muscle. Two distinct layers of fascia are contained within this unit. The deep temporal fascia, which is a continuation of the investing fascia containing the deeper temporalis muscle as it becomes continuous with the periosteum of the skull; and the superficial temporal fascia, which is a continuation of the SMAS as it connects to the galea aponeurotica (Fig. 1-12). In this region, the superficial temporal fascia is of anatomical and subsequent surgical importance as it contains within its layers key vascular and neural structures as they traverse between the fascial layers. The superficial temporal artery along with its branches and sensory nerves, including the auriculotemporal nerve, can be accessed within the layers of the superficial temporal fascia (Fig. 1-12). The motor branches of the facial nerve remain deep to the superficial temporal fascia as they course toward the deep surface of the orbicularis oculi and frontalis muscles (Fig. 1-6). The superficial temporal fascia forms a continuous layer with the galea aponeurotica, but splits medially to enclose the frontalis and orbicularis oculi muscles and laterally the superficial periauricular fibers. Inferiorly, the superficial temporal fascia is adherent to the zygomatic arch. Immediately adjacent to the superficial layer of the superficial temporal fascia, the subcutaneous fatty layer separates it from the overlying dermis. Fibrous septa create a more taut area as one moves toward the scalp, with relatively greater laxity just above the zygomatic arch. Numerous cutaneous vessels and nerves lie in this interval between the fat and fascia, which is important to remember when undermining in this area. The deep layer of the superficial

temporal fascia glides over the loose connective tissue of the deep temporal fascia, deep to which the temporalis muscle can be visualized (Fig. 1-12).

Figure 1-12. Dissection of superficial temporal fascia reflected to show superficial temporal vessels.

The primary source of vascular supply to the temple comes from the superficial temporal artery, a terminal branch of the external carotid artery. The superficial temporal artery emerges from the superior pole of the parotid gland as it pierces the parotid fascia anterior to the tragus (Fig. 1-12). Inferior to it, the transverse facial artery runs below and in line with the zygomatic arch. The artery is accompanied by the corresponding veins, and usually divides anteriorly into anterior and posterior branches, with two or sometimes three significant sized pedicles. The anterior branch follows a distinct tortuous course, especially prominent in elderly patients, to supply the temple and the temporal scalp region. Branches anastomose freely with the posterior parietal branches as well as contributions from the supraorbital artery. From an anatomical standpoint, it is important to note that while the superficial temporal artery lies within the layers of the superficial temporal fascia, the corresponding veins are located within the subcutaneous layer. As the arteries continue toward the scalp, they also come to lie within the subcutaneous plane just above the superficial temporal fascia.

Sensory innervation to the temple is achieved via the maxillary and mandibular divisions of the trigeminal nerve. The auriculotemporal nerve (Fig. 1-13) travels posterior and deep to the superficial temporal artery and

branches as it runs within the same fascial plane as the artery as they proceed toward the scalp. The skin adjacent to the lateral canthus is supplied by a branch of the maxillary artery, with the zygomaticotemporal nerve emerging from the lateral orbital wall. Additionally, the zygomaticotemporal nerve innervates an area of scalp between the territories of the auriculotemporal and supraorbital nerves (Fig. 1-8). Emerging from the superior pole of the parotid gland, the temporal branch of the facial nerve crosses superficial to the zygomatic arch as a single branch within the superficial temporal fascia increasing its vulnerability to surgical injury (Fig. 1-14). With the use of surface anatomical landmarks, the temporal branch may be visualized along a line 0.5 cm below the tragus to a point approximately 1.5 cm superior to the lateral edge of the eyebrow. The temporal branch of the facial nerve supplies the frontalis muscle from the deep lateral edge with few branches contributing to fibers of orbicularis oculi and those of surrounding muscles of facial expression.

Figure 1-13. Dissection of temporal region highlighting the auriculotemporal nerve.

Figure 1-14. Dissection demonstrating relationship between superficial temporal artery and temporal branch of the facial nerve.

Superficial orbital region and eyelid

- Skin of the eyelids is very thin with only a thin fascial layer between it and fibers of the orbicularis oculi muscle. There is no fat beneath the dermis.
- Lacrimal canaliculi are deep to the medial canthal tendon.
- The angular artery and vein cross the medial canthal tendon and contribute to an important site of anastomosis just superior to the tendon between branches of external carotid (facial artery) and internal carotid (ophthalmic artery).

The orbital rim is formed laterally by the zygomatic process of the frontal bone and the frontal process of the zygomatic bone. The frontal bone forms the superior orbital margin as well as the roof of the orbit, with the superciliary arch of the frontal bone defining the superior orbital rim.

Along the mid-pupillary line, the superior orbital rim presents a notch, sometimes a foramen ($>25\%$), known as the supraorbital notch/foramen, through which the supraorbital vessels and nerves are transmitted (Fig. 1-9).

The medial orbital margin is formed by the maxillary process of the frontal bone along with the frontal process of the maxillary bone. The maxillary bone forms the floor of the orbit and the infraorbital rim. The lateral canthus lies in contact with the sclera, whereas the medial canthus is separated from the sclera by the caruncle and the lacrimal lake. The caruncle contains sweat and sebaceous glands, whereas the lacrimal lake provides a collection area for tear fluid before passing through the lacrimal canaliculi.

The skin around the eyelids is very thin, with only a thin fascial layer between it and the fibers of the orbicularis oculi muscle. Unlike the usual anatomic relationship of skin to subcutaneous tissue, there is no fat beneath the dermis. Understanding this arrangement provides insight into the depth of dissection as the subdermal space is approached. There are no significant superficial nerves or vessels in this subfascial space. Additionally, skin over the tarsal plates is tightly adherent, whereas the preseptal area allows for greater mobility. Another point of importance when understanding the layers of tissue around the eye is to remember that the region over the orbital septum, just proximal to the tarsal region, presents with several layers. Following the skin, subcutaneous tissue orbicularis oculi, and orbital septum, there is a layer of orbital fat followed by the aponeurosis of the levator palpebrae superioris, Muller's muscle, and then conjunctiva (Fig. 1-15).

Figure 1-15. Diagram illustrating basic anatomy of the eye.

The orbicularis oculi and levator palpebrae superioris muscles are two predominant muscles of surgical concern. The orbicularis oculi is best described as two parts—the orbital portion and the palpebral portion. These portions of the muscle contract independently, the orbital portion under voluntary control and the palpebral fibers under both voluntary and involuntary control. The upper portion is innervated by the temporal branch of the facial nerve, whereas the lower fibers are innervated by the zygomatic branch of the facial nerve. The action is to tightly close the lids together. The orbital fibers attach to the orbital rim and blend in with the surrounding muscles of facial expression—the frontalis superiorly and the procerus medially. Corrugator supercilii lies beneath the medial aspect of the orbital fibers, and their origin from the medial orbital crest and insertion into the upper medial portion of the eyebrows bring the eyebrows medially.

The palpebral portion of the orbicularis oculi overlies the pretarsal and preseptal regions. Preseptal fibers cover the orbital septum of both upper and lower lids. It is important to note that the upper and lower preseptal fibers attach to the respective areas of the medial canthal tendon, and this arrangement has significant impact on the functioning of the lacrimal canaliculi. The continuation of these fibers laterally toward the lateral canthal tendon helps in bringing the lids together to produce winking and blinking actions. The pretarsal portion is attached firmly to the tarsal plate. Their connections maintain a similar anatomical arrangement as the medial and lateral preseptal muscles and are connected to the medial and lateral canthal tendons. The palpebral muscle unit is an important contributor to the mechanism of tear movement.

The medial canthal area is frequently a site for surgical excisions. Several important anatomical structures should be considered when working around this area. The lacrimal canaliculi are deep to the medial canthal tendon. However, they are secured at a deeper plane and relatively protected by an undisrupted tendon. The angular artery and vein traverse the area on their ascent within the nasolabial groove. They cross the medial canthal tendon and contribute to an important site of anastomosis just superior to the tendon between branches of the external carotid (facial artery) and internal carotid (ophthalmic artery) (Fig. 1-9).

The upper lid has two fat pads: the pre-aponeurotic and nasal units,²² and it may be difficult to distinguish between them and the lacrimal gland which lies in a lateral position on the upper lid. The lower lid contains a nasal,

central, and lateral fat pad. Their connection to the orbital septum laterally and via its fascia to the inferior oblique muscle medially makes the muscle susceptible to injury (Fig. 1-15). The levator palpebrae superioris and its aponeurosis are responsible for raising the eyelid, and are innervated by the oculomotor nerve. It is important to remember that the muscle arises in the apical region of the orbit and continues in its superior most location in an anterior direction. It is easily identifiable during dissection as it exists as a well-defined, flat, or sometimes more bulky muscle. As it approaches anteriorly, it divides into an aponeurosis, and posteriorly reflects into Muller's tarsal muscle. Fibers also attach to the orbicularis oculi and are connected to the overlying skin by fibrous strands. The lower lid is retracted by the extraocular inferior rectus muscle and also contains a tarsal muscle.

The tarsal plates are dense fibrous tissue plates that begin at the lacrimal puncta medially and extend to the lateral commissures. Numerous meibomian sebaceous glands are embedded vertically within the tarsal plates.^{4,22}

As previously mentioned, arterial supply to the eyelids is derived from extensive anastomosis between the internal and external carotid arteries. Branches from the ophthalmic, facial, and superficial temporal arteries perfuse both the upper and lower lids. Additionally, the maxillary artery via the infraorbital artery also contributes to the extensive vascularity, as its branches anastomose with the ascending branches of the transverse facial, facial, and angular arteries. The main venous drainage of the eyelids occurs via the superficial temporal, angular, and facial veins. Both arterial and venous systems present as vascular arcades along the upper and lower lids (Fig. 1-16).

Figure 1-16. Dissection demonstrating arterial arcades around the eyelids.

Nose

- The nose is divided into root, dorsum, lateral walls, tip, alae, and columella.
- Most of the alae are composed of skin and fibrofatty tissue.
- Blood supply is mainly from angular artery externally and the sphenopalatine artery internally, with smaller contributions from the superior labial and ophthalmic arteries.
- Sensory innervation is derived from infraorbital branch of the maxillary nerve and infratrochlear and external nasal branches of the anterior ethmoidal nerve (ophthalmic nerve).

The challenge with conducting surgery on the nose is twofold. On the one hand, the nose presents with complex anatomy consisting of skin, cartilage, and nasal mucosa within a rather small anatomical boundary. Secondly, the mid-face location of the nose places a premium on cosmetic outcome, which reinforces the importance of thoroughly understanding the anatomy that will facilitate effective surgical repair and outcome. In its simple description, the nose may be divided into the root, dorsum (bridge), lateral side walls, and

the lobule (Fig. 1-17). The lobule is further divided into the nasal tip, the infra-tip, and the alae. When viewed from below, the infra-tip lobule presents a soft triangular area anteriorly, a columella that extends inferiorly and separates two nostrils bound by the nostril sills, and laterally the alar base and rim. Together, the bony pyramid, septum, alar cartilages, and the cartilaginous vault form the main structural support of the nose.

Figure 1-17. Diagram illustrating basic anatomy of the nose.

The nasal bones articulate along the midline and with the frontal processes of the maxillae laterally. Superiorly, the nasal bones articulate with the nasal processes of the frontal bone and inferiorly with the perpendicular plate of the ethmoid bone. Nasal bones are thickest superiorly but thin out inferiorly where they may be easily damaged. There is an overlap between these lower and upper borders of the lateral cartilages. Skin over the bony pyramid is loose, fairly mobile, and can be easily undermined.^{22,23}

The lateral cartilages are a continuation of the nasal bones, being overlapped superiorly by these bones and inferiorly by the upper border of the lateral crura of the alar cartilages. Ligamentous tissue connects both these overhangs.

The nasal septum consists of bone, cartilage, and soft tissue which include all of its articulating craniofacial bony structures. A septal or quadrangular cartilage anchors to the perpendicular plate of the ethmoid bone and maintains structural integrity of the bony septum. The membranous septum, a soft tissue composite, consists of two layers of vestibular skin separated by loose connective tissue. Depressor septi muscle traverses the membranous septum and attaches to the inferior border of the septal cartilage.^{4,22}

The lobule is the most mobile portion of the nose due to the lack of any fixed cartilaginous joints. The support of the lobule comes from the paired alar cartilages suspended by soft tissue ligaments. The soft tissue portion of the ala does not contain cartilage but rather is structurally maintained by a thickened dermis with no underlying subcutaneous fat, making detecting an ideal dissection plane challenging in this area.

The key muscles around the nose include procerus, levator labii superioris alaeque nasi, nasalis, and depressor septi muscles. Procerus extends from the frontalis muscle across the root of the nose and blends in with the transversely positioned nasalis muscle. It is important to remember that the plane deep to nasalis is continuous with the subgaleal plane, which maintains a bloodless field of dissection. The levator labii superioris alaeque nasi arises from the maxilla and sends fibers to the medial upper lip and the lateral ala. The most medial portion of these muscle fibers is referred to as the depressor septi, which pulls down on the septum and keeps the airways patent ([Fig. 1-18](#)).

Figure 1-18. Diagram illustrating deeper anatomy around the nose.

The nose receives a rich blood supply which is a surgical advantage and allows for versatility in flap design and orientation. While blood supply is mainly from the angular artery externally and the sphenopalatine artery internally, with smaller contributions from the superior labial and ophthalmic arteries, the largest vascular contribution is derived from the external carotid system. The superior and inferior labial arteries are branches off the facial artery and they continue along the lateral aspects within the nasolabial grooves as the ascending angular artery en route to the medial canthal anastomotic site. The angular artery gives off many small branches to the sidewalls, ala, and dorsum, and form free and contralateral anastomoses terminating through a connection with the dorsal nasal artery (Fig. 1-19). This point of anastomosis is highly predictable, and its consistent presentation makes it a very viable pedicle for flap construction. The

glabella and mid-portion of the forehead is supplied by the supratrochlear artery, a branch of the ophthalmic artery that is also a reliable vascular pedicle in nasal reconstruction of the dorsum and tip of the nose (Fig. 1-20). Deep to the nasal bone, the external nasal artery emerges onto the dorsum of the nose (Fig. 1-21). It is usually accompanied by the external branch of the anterior ethmoidal nerve which supplies sensory innervation to the dorsum and tip of the nose. The infraorbital artery also contributes to vascular anastomosis around this area. Venous drainage follows the pattern of arterial supply and does not display any anatomy of significance.

Figure 1-19. Dissection demonstrating ascent of the facial and angular artery within the nasolabial region.

Sensory innervation to the nose is achieved through branches of the ophthalmic and maxillary divisions of the trigeminal nerve. Ophthalmic division supplies the area along the midline of the nose, whereas the maxillary division via the infraorbital nerve ([Fig. 1-20](#)) innervates the alae, lower lateral walls, and columella. The root and upper nasal bridge along with the upper lateral walls is supplied by the infratrochlear nerve that approaches the nose in a medial direction from above the medial canthal tendon.

Figure 1-20. Dissection of the anterior left cheek highlighting the infraorbital nerve.

Ear

- The external ear is divided into the auricle (pinna), the external auditory meatus and canal, and the external surface of the deeper set tympanic membrane.
- Blood supply to the ear is derived from superior and inferior auricular branches of the superficial temporal artery and the deep auricular branch of the maxillary artery.
- The external ear receives a rich sensory innervation from overlapping cranial and cervical nerves.
- The auriculotemporal nerve travels posterior to the superficial temporal vessels and supplies the anterior portion of the auricle and anterior helix.
- The auriculotemporal nerve lies posterior to the superficial temporal artery and vein, and exits the superior parotid fascia as it traverses the parotid gland.
- The mastoid area is supplied by C2, C3 ventral rami derived via the lesser occipital nerve. Concha is supplied by variable overlapping innervation from cranial nerves VII, IX, and X, which also supply the posterior aspect of the external meatus and tympanic membrane and posterior auricular sulcus.

For the dermatologic surgeon, understanding the architecture of the ear is essential to repairing both large and smaller defects. When undermining, performing a primary closure, or during mobilization, knowledge of the variation in skin thickness, elasticity, relationship to the underlying cartilage, and pattern of perfusion helps in producing the most effective repair.

The external ear is divided into the auricle (pinna), the external auditory meatus and canal, and the external surface of the deeper set tympanic membrane.²² The auricle consists of a complex cartilaginous framework that is thrown into folds and grooves. The cartilage is covered by tightly bound skin with very little subcutaneous tissue, often with no subdermal fat at all. While the skin is tight anteriorly, posteriorly it offers a little more flexibility. The most inferior portion of the auricle, the lobule, has no cartilaginous base and consists of subcutaneous fat and skin. There are two distinct curves that extend superior to the lobule: (1) the outer helix—an anteriorly curved fold that continues posterosuperiorly from the lobule toward the upper limit of the tragus where it blends in with the crus of the helix; and (2) the antihelix,

separated from the helix by a groove known as the scaphoid fossa. The tragus, an anterior extension of the auricular cartilage, is separated from the antitragus by the intertragal space. A deep concave groove referred to as the concha leads to the external auditory meatus. The concha is further subdivided into a more superior impression, the cymba, and an inferior, larger impression, the cavum (Fig. 1-22).^{4,9,22}

While variations exist, in its standard anatomical position the ear is situated laterally, lies somewhat between the eyebrows and the base of the nose with the helix protruding beyond the antihelix. Ligamentous fibers connect the auricle to the skull and contain rudimentary intrinsic muscles. Extrinsic muscles are of little clinical significance, but it is helpful to note that these muscles of facial expression—the anterior, posterior, and superior auricular muscles—are contained within the SMAS and innervated by branches of the facial nerve.

The length of the external auditory meatus and canal measures 2.5 to 3.5 cm. The canal itself has both bony and cartilaginous parts.²² Laterally, the cartilaginous component is continuous with the auricular cartilage, while medially, it is attached to the bony meatus. The cartilaginous portion is mostly present in the inferior aspect of the canal. Superiorly, the canal is bound by the squamous temporal bone. The true bony portion of the canal tunnels between the squamous and tympanic parts of the temporal bone. Around the lateral portion of the external meatus the skin is thicker, with sebaceous, cerumeniferous glands and hair. The bony portion contains very thin layer of epithelium and is devoid of hair and glands. Of particular clinical interest are the fissures within the cartilaginous portion of the canal. These randomly arranged fissures, known as fissures of Santorini, offer potential avenues for developing skin cancers to spread into surrounding tissue.

Figure 1-21. Superficial dissection of anterior nose demonstrating the external nasal nerve and vessels.

Figure 1-22. Diagram illustrating basic anatomy of the external ear.

The rich blood supply to the ear is derived from superior and inferior auricular branches of the superficial temporal artery and the deep auricular branch of the maxillary artery. Additionally, the posterior auricular artery, a branch of the external carotid artery, supplies the posterior aspect of the ear. Arterial branches are arranged as a single layer of vessels within the skin as a consequence of the sparsity of subcutaneous fat. The venous pattern

corresponds with the arterial supply, and drainage is via the superficial temporal and retromandibular veins.

The external ear receives rich sensory innervation from overlapping cranial and cervical nerves. The mandibular division of the trigeminal nerve gives off the auriculotemporal nerve, which travels posterior to the superficial temporal vessels and supplies the anterior portion of the auricle and anterior helix. Additionally, the auriculotemporal nerve supplies the anterior and superior walls of the auditory canal as well as a portion of the external surface of the tympanic membrane (Fig. 1-13). Injury to the auriculotemporal nerve may be limited by recalling that it lies posterior to the superficial temporal artery and vein and that inferiorly it exits the superior parotid fascia as it traverses the parotid gland. The great auricular nerve (C2, C3 ventral rami) supplies most of the medial surface of the auricle as well as the posterior portion of the lateral surface of the auricle. This will include most of the helix and antihelix. The mastoid area is also supplied by C2, C3 ventral rami but its innervation is derived via the lesser occipital nerve. The concha is variably innervated by cranial nerve VII, and the meatus is innervated by cranial nerves IX and X.^{4,9,22} These cranial nerves also supply the posterior aspect of the external meatus and tympanic membrane and posterior auricular sulcus.

Lips and Chin

- Orbicularis oris muscle has no bony attachment and is innervated by the buccal branch of the facial nerve through its deep surfaces.
- Blood supply is derived from superior and inferior labial arteries arising from the facial artery.
- Innervation of the upper lip is achieved via the infraorbital nerve (V2) and of the lower lip via the mental nerve (V3).
- Redundancy of skin as well as mucosa around the commissural junction enables mobility and flexibility when the mouth is opened.
- Sensory innervation to the chin is supplied by the mental nerve branches (V3).
- Lip depressor muscles and mentalis are innervated by the marginal mandibular branch of the facial nerve.

Surgery of the lips lends itself to both cosmetic and functional importance. Disruption of the architectural contour of the lips has far-reaching consequences for the patient, making preservation and restructuring of the anatomy of utmost importance. While not often considered, the lip constitutes more than just the vermilion.²² It extends superiorly to the nose and inferiorly to the chin, corresponding with the circularly arranged fibers of the orbicularis oris muscle. The boundary line of the upper lip lies at the junction of the columella, nasal sill, and alar crease below the base. Laterally, the upper lip extends to the nasolabial fold, a point at which the lip elevators insert into the orbicularis oris fibers. The upper lip is divided by a vertically placed philtrum bound by philtral columns on either side and inferiorly by a downward arch referred to as Cupid's bow. The vermilion is composed of a modified mucosal membrane with a rich underlying vascular supply. There are no underlying sweat, salivary, or sebaceous glands.^{4,22} A redundancy of skin as well as mucosa around the commissural junction enables mobility and flexibility when the mouth is opened. A group of muscles of facial expression for elevation, depression, and retraction insert deep to the commissural skin.

The underlying anatomy of the lip is not complex, and contains the orbicularis oris fibers covered by mucous membrane (toward the oral cavity) and skin. The muscle fibers have a very close relationship with the dermis via muscular slips, limiting the ease with which dissection and reflection of the skin are possible. Bulging of the muscle fibers creates a corresponding surface marking known as the "white roll" or "white line" along the vermilion–cutaneous junction.^{4,9,22} Orbicularis oris muscle has no bony attachments, and is circumferentially arranged to facilitate sphincteric action.

Motor innervation of the orbicularis oris is derived from the buccal branch of cranial nerve VII. Most of the angle elevators as well as the lip itself are supplied by the buccal branch. As the buccal branches exit the parotid fascia, they flank the parotid duct as they travel medially toward the orbicularis fibers to then pass deep to the muscle, innervating it from the deep surface (Fig. 1-23). The marginal mandibular branch of cranial nerve VII contributes to the depressors, again passing through the deep surface of the muscles. Sensory nerves are abundant and derived from the infraorbital branch of the maxillary nerve (CN V₂) (Fig. 1-24) reaching the upper lip, and from the mental nerve (terminal branch of the inferior alveolar nerve, a

branch of mandibular nerve CN V₃) reaching the lower lip. Numerous small branches are encountered upon reflection of the skin. The main nerve trunks, however, may be accessed at the infraorbital foramen and the mental foramen. The infraorbital and mental foramina are generally located in a fixed position relative to the alae and oral commissure, respectively.

Figure 1-23. Dissection of the lateral face with skin and subcutaneous layers reflected medially.

Figure 1-24. Anterolateral view of lower face with skin and subcutaneous tissue over upper lip reflected inferiorly.

Blood supply to the lips is achieved through an anastomotic arterial arcade formed by the superior and inferior labial arteries (Figs. 1-24 and 1-25). These branches arise from the facial artery around the angle of the mouth. However, oftentimes the inferior labial artery may originate at a lower point, as the facial artery crosses over the angle of the mandible. With this branching pattern, the inferior labial artery may lie lower than its normal position and ascend toward the midline of the chin. Both the superior and inferior labial arteries are often highly tortuous, especially in older individuals, and run deep to the fibers of orbicularis oris. Skin over the lips is supplied by vertically ascending and descending branches off the arcades.

Figure 1-25. Lateral view of dissection of regional anatomy around the mid cheek and mandibular region.

The chin is a relatively fixed anatomical structure that is composed mostly of muscles of facial expression acting on the lower lip. The chin extends from the mentolabial crease to the most inferior point along the midline of the mandible. In older individuals, RSTLs are visible and can be distinguished between (1) the radially extending lines around the lower lip area with diagonal extensions toward the angles of the mouth and (2) the variable lines

around the mental region that are determined by the shape of the chin.²² As the muscles of facial expression insert directly into the skin, very little subcutaneous tissue is found in this area. Creating a dissection plane is somewhat difficult as the taut insertion of the muscles limits undermining in this region.

Muscles of the chin include overlapping fibers of the orbicularis oris muscle that mingles with the fibers of the platysma and other surrounding regional muscles. Laterally, the depressor anguli oris attaches to the medial aspects of the mandible and the oral commissure to pull the angle of the mouth downward. On the front of the mandible, the depressor labii inferioris is partially overlapped by the depressor anguli oris. Two slips of the mentalis muscle arise from the mandibular midline and insert onto the skin of the chin, maintaining a variable gap between them (Fig. 1-3). All these muscles are supplied by the marginal mandibular branch of the facial nerve. The marginal mandibular nerve is easily visualized as it passes along the bony margin to enter the chin deep to the angle of the mouth. Since the marginal mandibular nerve is often seen as a single exposed trunk before branching to supply these muscles, injury to the trunk will result in unopposed action of the antagonists of these muscles (Fig. 1-26).

Figure 1-26. Dissection highlighting the marginal mandibular branch of the facial nerve and its relationship to the facial artery.

The mental nerve exits the mental foramen as a terminal branch of the inferior alveolar nerve. It is a purely sensory nerve and displays a tuft-like branching pattern. With aging, mandibular bone resorption may change the relative location of the mental foramen, bringing it a little higher toward the superior margin due to the decreasing height of the alveolar processes.

Cheek

- The anterior region includes the buccinator muscle, buccal fat pad, buccal branches of the facial nerve, and the downward traversing parotid duct.
- The parotid region is dominated by the parotid gland and underlying deep masseter muscle.
- The parotid duct and facial artery are easily identifiable landmarks in this region.

- The marginal mandibular nerve is a key structure in the mandibular region as it consistently crosses the facial artery deep to the fibers of platysma.

Anatomically, the cheek extends from the anterior border of the ear, limited medially by the nose, lips, and chin, and from the mandible up to the zygomatic arch and orbital rim. However, to best appreciate the cosmetic unit of the cheek, it is best described in three regions: the anterior, mandibular, and masseter–parotid regions.^{4,9,22}

The *anterior region* contains many of the muscles of facial expression. The risorius is very superficial and of variable size, sometimes even absent. The zygomaticus major and minor as well as the levator labii superioris and the levator labii superioris alaeque nasi originate from the zygomatic bone and orbital rim, and are overlapped by the fibers of the orbicularis oculi muscle. When reflecting the skin over this region, zygomaticus minor is seen more superficially than the rest of the muscles, with only a few millimeters of subcutaneous tissue overlying it (Figs. 1-6 and 1-23). Since the facial nerve branches maintain their course and innervation deep to the muscles, injury to these branches is less likely provided that the plane of dissection remains superficial to the muscle plane.

Along the medial aspect of the anterior cheek, the facial artery can be seen anterior to the facial vein after crossing the mandible to ascend toward the angle of the mouth where it gives off the labial branches and subsequently traverses the nasolabial groove as the angular artery. Within the nasolabial groove, the angular artery can be accessed with little difficulty by dissecting within the subcutaneous tissue and overlying muscle slips of the zygomaticus major and minor muscles (Fig. 1-19). The angular artery then terminates at the medial canthus just above the medial canthal tendon by anastomosing with the ophthalmic branch of the internal carotid artery (Fig. 1-19). The deepest structures in this region of the cheek are the buccinator and levator anguli oris muscles. Unlike the other muscles of facial expression, the buccinator is a relatively fleshy muscle. It lies within a drop-down plane covered by a significant amount of fatty tissue, often referred to as the buccal fat pad (Fig. 1-25). The buccinator is pierced by the parotid duct as well as blood vessels and buccal branches of the maxillary nerve en route to supply sensory innervation to the buccal mucosa.^{4,9,22} The buccal fat pad itself lies technically in the medial cheek. This fatty mass is well defined and contained

by a thin layer of fascia, and on its surface the facial nerve branches can be visualized crossing over the fat pad still deep to the SMAS (Fig. 1-6). Superiorly, the infraorbital nerve branches out as a leash of nerves to supply sensory innervation to the medial cheek. The supraorbital foramen is easily palpated on most individuals.

The *masseter–parotid region* offers a very important anatomical landmark—the deeply set masseter muscle. A muscle of mastication supplied by the trigeminal nerve, the masseter can be easily visualized and palpated when the jaw is clenched. Its strong attachments extend between the zygomatic arch and the ramus of the mandible, and its anterior musculotendinous border provides an important landmark for key facial structures. The posterior half of the masseter is covered by the parotid gland. Contained within its own fascia, the parotid gland, wedged along the preauricular mandibular region, is separated from the masseteric fascia which is a continuation of the superficial layer of deep cervical fascia. The lower anterior portion of the masseter may be overlapped by the fibers of the platysma in most individuals.

When visualized on unembalmed cadaveric specimens, the parotid gland displays a yellowish color, very similar to the living patient. It may sometimes be confused with subcutaneous fat as it is relatively close to the skin itself (Fig. 1-23). Unlike the subcutaneous tissue, however, the parotid gland is contained within a shiny, tight fascial sheath, the parotid fascia, which may help in differentiating it from fat. On the anterior border of the gland, the parotid duct can be located as it travels horizontally and then downward into the buccal fat. It consistently crosses over the masseter muscle before turning sharply toward the buccinator to pierce it and enter the oral cavity opposite the upper second molar. From its surface anatomy, the parotid duct may be located in the region of intersection between the tragolabial line,²² and the anterior edge of the masseter muscle and, additionally, along the zygomatic arch about 2 cm below it. The parotid duct is a prominent structure and provides a reliable anatomical landmark. As the parotid duct lies deep to the SMAS, it is crossed by fibers of the zygomatic branch of the facial nerve and also flanked by the upper and lower buccal branches of the facial nerve (Figs. 1-5, 1-6, and 1-23).

The transverse facial artery, arising from the external carotid artery, passes parallel to the parotid duct between it and the zygomatic arch. It also crosses over the anterior margin of the masseter muscle. The superficial

temporal artery exits the parotid fascia below the zygomatic arch just anterior to the tragus (Fig. 1-27).^{4,9,22} It passes posterior and deep to the parotid gland as one of the terminal branches of the external carotid artery. The facial artery and vein (posterior to the artery) also travel beneath the SMAS as they cross over the mandible. The facial artery and vein can be located just anterior to the masseter muscle. The facial artery, which travels in a tortuous ascending course, is often more prominently tortuous in older individuals. The mandibular branch of the facial nerve crosses over the facial artery about 5 to 10 mm above the point at which the facial artery crosses the mandible.

Figure 1-27. Diagram illustrating the arterial pattern and supply to the face.

The mandibular region extends from the anterior margin of the masseter muscle to the chin. Three predominant muscles are encountered after reflecting the skin in the region. The platysma lies within the superficial fascia and inserts into the skin of the lower lip, blending in with the fibers of the orbicularis oris muscle. The depressor anguli oris, which originates on the mandible and inserts onto the angle of the mouth, also sends fibers that blend in with those of the platysma and orbicularis oris.

Both the facial artery and the marginal branch of the facial nerve lie deep to the fibers of the platysma. In most individuals, the marginal branch of the facial nerve maintains a course above the mandibular rim, crossing the facial artery to supply the depressors of the lips and the mouth. While there are

usually two branches, the mandibular branch of the facial nerve can exist as a single nerve or have as many as four branches (Fig. 1-26).

SURGICAL CONSIDERATIONS

Muscles of the face

The muscles of facial expression and the superficial group of muscles of mastication form the basis for the muscular framework of the face (Fig. 1-3). Muscles of facial expression lie at varying depths just deep to the subcutaneous tissue. They attach from the facial skeleton to the overlying dermis in a 3D configuration from deep to superficial.^{2,3,6,14,27} Seen from this four-layered overlaying construct, the deepest muscles include buccinator, mentalis, and levator anguli oris. At the next level, the orbicularis oris and levator labii superioris can be visualized, followed by the more superficial depressor labii inferioris, risorius, platysma, zygomaticus major, and levator labii superioris alaeque nasi. Fibers of the depressor anguli oris, zygomaticus minor, and orbicularis oculi can be identified most superficially. All the muscles (except for the deepest layer) are innervated by the branches of the facial nerve passing through their deep surfaces.^{4,9}

Branches of the facial nerve

Facial nerve branches, while generally protected by the SMAS, are surgically vulnerable as they reach areas of transition along their course toward their final destination.

Injury to the facial nerve and its branches during surgical exposure has been a topic of detailed discussion.^{2,5,6,15,28–32} A few key points can help guide dissection around facial nerve branches: (1) Facial nerve exits its intracranial course through the stylomastoid foramen and immediately gives off the posterior auricular nerve which passes behind the ear toward auricularis posterior and the occipital belly of occipitofrontalis muscles. (2) At the posteromedial surface of the parotid gland, just before this point or within the gland, the facial nerve branches into a superior temporofacial and inferior cervicofacial division. (3) Facial nerve divides and reconnects through an extensive branching pattern before it exits the parotid fascia along

the medial margin to give rise to five main trunks: temporal, zygomatic, buccal, mandibular, and cervical.^{4,9,29} (4) Main branches lie within the parenchyma of the parotid gland and are not at risk for injury during superficial surgical procedures unless the parotid gland or parts of it have been resected (Fig. 1-4). (5) Vulnerability to injury of the facial nerve branches increases as they travel toward their areas of innervation. (6) Facial nerve branches are most susceptible to injury in their transition from Layer 5 (deep fascial plane) to Layer 4 (soft tissue spaces).^{2,15,29} (7) Along their course, branches of the facial nerve lie deep to the SMAS and can be safely encountered as long as the plane of dissection is maintained above the SMAS (Fig. 1-6).

Anatomic points of consideration to limit vulnerability of facial nerve branches to injury

1. Temporal branches emerge from the upper margin of the parotid fascia and cross the zygomatic arch. Usually three to four branches supply frontalis and parts of orbicularis oculi (Figs. 1-4, 1-6, and 1-14).
2. Zygomatic branches cross the zygomatic arch and bone and are in direct contact with periosteum. As they cross the bony eminence, they lie directly under the skin with no subcutaneous protection (Figs. 1-4, 1-6, and 1-23).
3. Buccal branches flank the parotid duct along its upper and lower margins. Keeping the parotid duct in view helps maintain a safe zone limiting injury to the buccal branches as they travel toward the buccinator, nasalis muscle fibers, and the upper portions of the orbicularis oris muscle (Figs. 1-5 and 1-23).
4. The marginal mandibular branch travels frequently as a single branch, and often as two branches running above, along, or about 1 cm below the inferior border of the mandible. It consistently crosses over the facial artery, making it vulnerable to injury once the facial artery is approached. The platysma offers a layer of protection over the marginal mandibular branches and the mandible-traversing portion of the facial artery (Fig. 1-26).
5. The cervical branch is located deep to the platysma as it descends from the lower border of the parotid gland maintaining its position on the deep

surface of the muscle. It is only vulnerable to injury if the fibers of platysma are reflected (Fig. 1-23).

Anatomic points of consideration to avoid injury and maximize vascular sources for reconstruction

The superficial arterial supply to the face includes a rich anastomotic network of branches originating from the external and internal carotid arteries. Through extensive anastomoses, these major vascular trunks provide reliable pedicles and contribute to the microvascular infrastructure of the superficial face. The external carotid artery includes a vast network of arborizing, anastomotic, and tortuous arteries varying in size and depth within the fascial planes. The internal carotid artery via its ophthalmic branch supplies a central triangular area including the eyes, superior nose, and central portion of the forehead.^{4,9} The key area of anastomosis between external and internal carotid arteries is located above the medial canthal tendon where the angular artery communicates with the dorsal nasal branch of the ophthalmic artery (Fig. 1-19).

The superficial temporal artery ascends behind the temporomandibular joint, anterior to the tragus and auriculotemporal nerve. It crosses the zygomatic arch and branches over a wide surface deep to the skin and within the layers of the superficial temporal fascia. The supraorbital and supratrochlear arteries run along the same territory as a neurovascular bundle with the supraorbital and supratrochlear nerves. The larger supraorbital artery usually anastomoses with the superficial temporal artery (Fig. 1-12).

The anastomosis of the angular branch of the facial artery with the dorsal nasal artery above the medial canthal ligament is an area of surgical importance (Figs. 1-10 and 1-19). While the course of the facial artery within the nasolabial fold is well known, its infrequent course outside the fold has been documented. The artery has been recorded passing through the fold in up to 90% of individuals, and at least 5 mm outside the territory or crossing it in up to 45% of individuals.^{10,33} In the nasolabial region, the facial artery along with its superior and inferior labial arteries may not always maintain a submuscular position. Lee et al.³³ provide anatomical evidence for the vessels travelling superficial to the surrounding muscles of

facial expression and sometimes looping deep and superficial to the muscle fibers.

Anatomy of the neck

Understanding the superficial anatomy of the neck begins with the ability to visualize key structures bound by palpable landmarks. The topographic anatomy of the neck is marked by consistent musculoskeletal structures that present triangular spaces seen from the anterior and lateral aspects (Fig. 1-28). Surgical approaches to the neck can be enhanced by keeping the following anatomical points in perspective:

Figure 1-28. Diagram illustrating the anatomical boundaries and structures within the posterior triangle of the neck.

1. The most prominent landmark in the neck, the sternocleidomastoid muscle (SCM), provides the primary boundary for differentiating the anterior and posterior triangles.
2. The most superficial muscle of the neck, the platysma, is invested by superficial cervical fascia (continuous with the SMAS), creating a thin

muscular veil over the superficially traversing cutaneous nerves.

3. Superficial cervical nerves, the great auricular, lesser occipital and transverse cervical nerves, are encountered at the posterior border of the SCM when platysma muscle is reflected.
4. Erb's point, located 6 cm below the midpoint of a line connecting the angle of the mandible with the mastoid process, provides a landmark for the exit point of the superficial cervical nerves and the accessory nerve (cranial nerve XI).³⁴
5. The external jugular vein travels along a vertical course on the superficial surface of SCM anterior to the great auricular nerve to the base of the neck where it pierces the deep cervical fascia.

Triangles of the neck

The triangles of the neck are formed by visible and palpable landmarks of its musculoskeletal framework. The anterior triangle is bound posteriorly by the anterior margin of the SCM, superiorly by the inferior margin of the mandible, and anteriorly by the sternohyoid and sternothyroid muscles. The posterior triangle is bound anteriorly by the posterior border of the sternocleidomastoid and posteriorly by the anterior border of the trapezius muscle and lateral portion of the clavicle (Fig. 1-28).

The anterior triangle may be further subdivided by the posterior and anterior bellies of the digastric muscle and hyoid bone into the submental, submandibular, carotid, and muscular triangles (Fig. 1-29).

Figure 1-29. Diagram illustrating the sub-divisions of the triangles of the neck.

- **Submental triangle:** The flat mylohyoid muscle forms the floor, with the nerve to mylohyoid running along this surface; it contains few structures of significance other than subcutaneous fat, fascia, and lymph nodes.
- **Submandibular triangle:** The submandibular gland is the most prominent structure. It contains lymph nodes and the proximal portion of the facial artery as it courses between the parts of the submandibular gland; the low-hanging marginal mandibular branch of the facial nerve passing below the mandibular margin must be considered within this space.

- **Carotid triangle:** The carotid sheath containing the common carotid artery, internal jugular vein, and vagus nerve fills the space. The ansa cervicalis (branch of cervical plexus) motor contribution to strap muscles loops over the anterior surface of the carotid sheath; internal and external carotid arteries originate within this triangle; the hypoglossal nerve may be seen as it travels along the uppermost portion of the triangle from posterior to anterior.
- **Muscular triangle:** Contains the strap muscles (infrahyoid), including sternohyoid, sternothyroid, omohyoid and thyrohyoid muscles, and traversing muscular branches of the cervical nerves.

The posterior triangle ([Fig. 1-28](#)) can be further divided anatomically by the inferior belly of the omohyoid into the occipital and supraclavicular triangles. However, these divisions are rarely differentiated clinically. The deepest aspect of the posterior triangle, the floor, is formed by the parallel arrangement of deeper, smaller, neck muscles. Superiorly, the triangle contains the splenius capitus. Inferiorly, the levator scapulae (an important muscular landmark for isolation of the accessory nerve) lie above the posterior and middle scalene muscles. It is surgically useful to note that these muscles are covered by the prevertebral fascia (deep cervical fascia) on the top of which lies the superficial layer of deep cervical fascia.

In the next layer, two important nervous structures lie over and between the muscles of the floor of the posterior triangle. The proximal portion of the trunks of the brachial plexus lie anterior to the middle scalene muscle and are covered by the overlying prevertebral fascia. Injury to the trunks of the brachial plexus is unlikely as long as the prevertebral fascia remains uninterrupted.

Perhaps, one of the most emphasized structures of surgical interest in the posterior triangle is the accessory nerve (CN XI) ([Fig. 1-30](#)). As it descends over the levator scapulae muscle to pass beneath the trapezius muscle, the course of the accessory nerve can be traced along the midline of the posterior triangle. As the accessory nerve contains primary motor fibers to the trapezius muscle, injury during deeper surgical excisions will result in impaired function of the trapezius muscle (symptoms include winged scapula, inability to shrug shoulders, pain, initiation of arm abduction). The accessory nerve also provides motor innervation to the SCM muscle, but its branches to the SCM are less likely to be injured as they innervate the muscle on its deep

surface. In the posterior triangle, the accessory nerve is most vulnerable to injury in the 3- to 4-cm area between SCM and trapezius muscles. The accessory nerve can be distinguished from the surrounding cutaneous cervical nerves at Erb's point,³⁴ as it passes posteriorly along a diagonal course to become almost vertical within the posterior triangle. The great auricular nerve traverses the SCM, while the lesser occipital nerve remains close to the muscle along its ascent. The transverse cervical nerve passes horizontally across SCM in an anterior direction. During dissection, cervical nerves carrying proprioceptive fibers can be seen in a slightly more superficial plane travelling along the course of the accessory nerve. While the accessory nerve is a superficial structure and very vulnerable to surgical injury, it is still offered a layer of fascial cover as it lies between the prevertebral and superficial layers of deep cervical fascia. A consistent carpet of fatty tissue lies beneath the accessory nerve. The thickness of subcutaneous tissue of the superficial fascia over the nerve can vary between individuals. Additionally, proprioceptive fibers from the cervical plexus can be seen communicating with the accessory nerve and may sometimes be confusing when identifying the accessory nerve itself (Fig. 1-30).

Figure 1-30. Superficial dissection of the posterior triangle of the neck with detailed demonstration of the key regional nerves.

The layered organization of anatomical structures presents access to safe dissection planes. When performing surgery on the neck, appreciating the organization of the fascia allows the surgeon to maintain integral anatomy while safely accessing clinically targeted structures or areas. Fascia of the neck can be differentiated into superficial fascia and deep fascia. The superficial fascia is often synonymous with the subcutaneous tissue, but in the neck, the platysma is contained within it and shares the same relationship that

the muscles of facial expression have with the SMAS. The deep cervical fascia, on the other hand, is further separated into three layers. The superficial layer and deep layer completely surround the neck while the middle layer is discontinuous. The investing layer of deep cervical fascia (superficial) splits to surround the SCM, trapezius, and strap muscles (connecting the sternum to the laryngeal framework). As this layer covers the posterior triangle of the neck, it also forms a fascial layer over the cervical cutaneous and accessory nerves. The deep layer of deep cervical fascia (prevertebral fascia) covers the deeper layer of neck muscles as well as the scalene muscles, thereby also forming the floor of the posterior triangle of the neck (Fig. 1-30). In the posterior triangle of the neck, the deep layer of deep cervical fascia overlays the trunks of the brachial plexus as well as the phrenic nerve which travels on the anterior surface of the anterior scalene muscle (Fig. 1-31). Pretracheal fascia can only be found on the anterior aspect of the neck. It arises from the superficial layer of the deep cervical fascia and overlies the thyroid gland, laryngeal structures, and trachea.

Figure 1-31. Deeper dissection of the posterior triangle demonstrating anatomical structures beneath fatty carpet.

As the plane beneath the platysma is entered, branches of the cervical plexus become distinctly visible. Care should be taken to avoid injury to

these nerves, even though their disruption results in nothing more than loss of cutaneous innervation, possible formation of neuromas must also be considered.

The great auricular nerve (Fig. 1-30) derived from the second and third cervical nerve loops, passes around the SCM almost vertically to the skin of the ear lobe. It can be quite adherent to the overlying fascia and is the largest of the cervical nerves in that region. Additionally, it supplies cutaneous innervation to posterior portion of the ear, inferior parotid, and mastoid areas.

The lesser occipital nerve (Fig. 1-30), also derived from the second and third cervical nerves, passes close to the posterior edge of SCM in a superior trajectory. It innervates the skin behind the ears and parietal scalp.

The transverse cervical nerve (Fig. 1-30) arises from the second and third cervical nerves, and passes horizontally across the SCM. It fans out to supply the skin over the anterior aspect of the neck.

Additionally, the supraclavicular nerves (usually three to four branches) arise from the third and fourth cervical nerves to pass inferiorly and supply skin over the supraclavicular triangle, sternum, deltoid region, lateral clavicle, and upper posterior trapezius area.

CONCLUSIONS

This anatomy discussion is intended to serve as a preoperative review and a conceptual framework for guiding the dermatologic surgeon. The concepts presented are based on reviews regarding clinically significant anatomy as well as established descriptions of normal anatomy, but in particular from recordings of detailed microdissection of a series of latex-injected fresh frozen cadavers. Anatomical descriptions have been designed to specifically enhance perspectives for the dermatologic surgeon in the hope that its understanding will decrease surgical hesitance and promote advances toward better tissue repair. Visualization of a layered system will strengthen the understanding of the course and location of important neurovascular structures as they travel in a stepwise pattern in and between the muscular, bony and fascial planes to reach their terminal areas of supply and innervation. Standard descriptions of the neurovascular distribution and patterns provide a limiting 2D view of structures travelling within a 3D

configuration. Understanding the relative depth, course, and variability of key structures as they traverse anatomical boundaries provides the key to successful surgery.^{6,8,35–43}

CHAPTER 2 Wound Healing and Surgical Wound Dressings

Amy Vandiver
Luis Garza

SUMMARY

- Acute postsurgical wounds follow an orderly progression in healing, from hemostasis/inflammation to proliferation, and on to maturation and remodeling.
- Minimizing tension during primary wound closure will help limit the proliferative phase of wound healing and decrease chances of keloid formation.

- Simple wound dressings, such as polymer films, are generally adequate for most postoperative wounds.

Beginner Pearls

- Avoid dressing a wound with gauze directly adjacent to the wound bed, as it has a tendency to become incorporated into the wound.
- An ounce of prevention truly is worth a pound of cure; pay attention to meticulous suturing and wound closure, and dressing choice will be far less important.
- Be sure to affix the pressure dressing to the surrounding skin and not to the polymer film, or when the pressure dressing is removed the film will be as well.

Expert Pearls

- While polymer films, such as Tegaderm, may work well for wounds closed with buried sutures alone, nylon sutures that will require removal in under a week may be best dressed with nonadherent pads.

Don't Forget!

- When using a polymer film dressing, some moisture under the dressing is desirable, but excess serous drainage may lead to maceration.
- Most surgical wounds do not require topical antibiotic dressings or ointments.

Pitfalls and Cautions

- Wound debridement is of vital importance, but can be painful. In general, the removal of necrotic tissue is fairly painless, though pretreatment with local anesthetics may be desirable.
- Expensive wound dressings and devices generally add little (other than expense) to the healing of well-sutured operative wounds.

Patient Education Points

- When using clear polymer films, advise patients that they will likely see some serous drainage or even frank bleeding under the dressing. A small amount of eschar present under the film is not concerning.
- Patient education regarding leg elevation and compression after lower leg procedures is of vital importance.

Billing Pearls

- While wound dressings are incorporated as part of any surgical procedure, debridement may be separately billable using the debridement codes (11042 series). Wound debridement performed during the postoperative global period, however, cannot be billed separately.

CHAPTER 2 Wound Healing and Surgical Wound Dressings

INTRODUCTION

Acute wounds are created with every surgical procedure, and outcomes are generally dependent on the wound-healing process. As dermatologic surgery frequently involves cosmetically sensitive areas such as the face, wound healing is of particular importance; even on the trunk and extremities, however, most patients tend to judge the success of their dermatologic surgery procedure more on the basis of the final scar appearance than on the low rate of recurrence.

The healing process is highly dependent on a patient's underlying health status, and complications such as surgical-site infections (SSIs), chronic wound development, and keloid scarring are common. In the United States, over 70 million surgeries are performed a year, with an estimated 38 million patients requiring acute postsurgical wound care.¹ Proper postsurgical wound care is the surgeon's first-line defense against morbidity.

Basic biology of wound healing

Three phases of acute wound healing

The biological process of healing an acute wound is coordinated across many cell types and physiological systems. It is classically described as consisting of three phases: an initial response in which hemostasis and

inflammation dominate, followed by a proliferative phase, followed by a period of maturation and remodeling (Table 2-1).²⁻⁴

Table 2-1. The Acute Wound Healing Process

Hemostasis/ Inflammation	Proliferation	Maturation/ Remodeling
Hours	Days	Weeks

Hemostasis and inflammation. In the initial phase of wound healing, local injury triggers recruitment of inflammatory cells. Wounding is accompanied by vascular injury and exposure of subendothelial collagen, which activates the intrinsic clotting cascade to aggregate platelets and form a fibrin clot. The damaged parenchymal cells and activated platelets then release multiple cytokines and growth factors, including platelet-derived growth factor and TGF- β , which attract inflammatory cells and fibroblasts to the site of injury. The established fibrin clot then serves as a scaffold for recruited cells. Following coagulation, cells migrate to the site of injury in waves. Neutrophils arrive first and play an antimicrobial role, phagocytizing bacteria or other foreign particles. Next, monocytes from the blood stream enter the wound site and are activated by platelet-released factors and the extracellular matrix to release multiple factors necessary for a continued inflammatory response and recruitment of fibroblasts, including CSF-1, TNF- α , PDGF, and nitric oxide.^{5,6}

Proliferation. During the proliferative phase of wound healing, granulation tissue and a new epithelial layer are formed. Granulation tissue begins forming 2 to 4 days after wounding when fibroblasts from neighboring dermal tissue are activated by release of growth factors including PDGF and EGF. These cells replicate and migrate into the matrix produced by the initial clot. Triggered by interactions with the clot, they secrete enzymes that break down the existing matrix and produce type III collagen to build a new matrix. Also during this period, angiogenesis is initiated, stimulated by factors released by macrophages and epidermal cells in response to damage and local hypoxia (Fig. 2-1).

Figure 2-1. Overview of proliferative phase wound-healing activity.

Reepithelialization is initiated soon after wounding when epidermal cells at the wound edge dissolve their basement membrane connections, alter their integrin presentation and cytoskeleton and begin migrating into the wound site, separating the clot products from underlying viable tissue.⁷⁻⁹ Next, the remaining epidermal cells at the wound margin proliferate and migrate over the provisional matrix. Once an intact cell layer is formed by proliferation and migration, basement membrane attachments and integrin expression revert to baseline state.

Maturation and remodeling. For wounds in which the edges were not approximated by external means, a process of wound contracture occurs over 2 to 3 weeks following wounding. This process is mediated both by fibroblasts moving on the collagen matrix and the presence of specialized myofibroblast cells which can be detected beginning 6 days after wounding.¹⁰ After contracture is complete, the wound remains weak, reaching approximately 20% of its final strength.¹¹ Over the next several weeks, the matrix undergoes a slower process of remodeling during which matrix metalloproteinases break down the existing type III collagen ECM and fibroblasts synthesize the stronger type I collagen.¹² By 3 months after

wounding; the scar tissue will reach its maximum strength, around 80% of the tensile strength of normal tissue.¹¹

Factors affecting wound healing

The ability of the carefully orchestrated process of wound healing to proceed in a timely and organized manner is highly dependent on optimal physiologic status. The level of bacteria, moisture balance, and tissue oxygenation, all have large impacts on a wound's ability to heal. Regarding bacteria, it is the level and type of bacterial burden that determines whether infection will spread and inhibit healing. A bacterial load of $>10^5$ per gram of tissue impairs closure regardless of method, as does the presence of any level of beta-hemolytic streptococcus.¹³ When the load is elevated, the inflammatory stage is prolonged and bacteria excrete enzymes that disrupt formation of ECM.

The impact of oxygenation varies throughout healing. While initial localized hypoxia stimulates proliferation, prolonged hypoxia is detrimental, triggering endothelial cell apoptosis and diminishing the essential activity of both neutrophils and fibroblasts.^{14,15} Coupled with the importance of maintaining perfusion, local edema and elevated tissue pressures play a detrimental role in wound healing by creating local ischemia. Pressure-related ischemia is a detrimental factor for healing in patients with low oncotic pressures, with venous-related edema and lymphedema, and in tissues which sustain elevated pressure during activity, such as bony prominences or feet.¹⁶

Evidence has shown that sufficient moisture is also necessary for proper healing. Excessive drying can lead to eschar formation and necrosis, while maintaining a moist environment facilitates the action of cytokines and formation of a preliminary ECM.^{17–19} However, excessive moisture can also be detrimental, leading to maceration of surrounding tissue and preventing appropriate formation of granulation tissue.²⁰

Patient factors

The ability of a wound to heal is strongly affected by the patient's underlying nutritional status, age and health status, and the underlying integrity of the wound site. It is important to consider these factors when evaluating a

patient's potential for healing and need for specialized wound care. Healing-related factors to consider in a patient's initial history and physical are noted in [Table 2-2](#).

Table 2-2. Considerations for Preoperative History and Physical to Predict Wound Healing

Healing-Focused History and Physical
<i>History</i>
Prior surgeries with prolonged healing
Prior keloid scarring
Prior lymph node dissection
Prior radiation
Recent HbA1c
Nutritional history
Use of steroids
Smoking history
Family history of prolonged healing
Dermatologic conditions
<i>Physical</i>
Body mass index
Perfusion distal to wound site
Local edema
Quality of scarring throughout body

Malnutrition has a negative effect on multiple processes of wound healing. The amino acids methionine and arginine are specifically implicated in cellular proliferation, matrix building, and angiogenesis. Multiple trace metals and vitamin C are all implicated in collagen synthesis, supporting the observation that patients with poor nutrition status have lower ability to rebuild an ECM.²¹

Obesity and hyperglycemia are also detrimental to healing. Obese individuals experience a higher rate of wound dehiscence, SSI, and pressure

ulcers,²² attributed to reduced perfusion of adipose tissue and systemic inflammation.^{23,24} Patients with diabetes also have pathologic inflammation in normal tissue, coupled with decreased migration of inflammatory cells, fibroblasts, and keratinocytes impairing progression of wound healing.^{25,26} Many diabetics also have vascular abnormalities leading to impaired delivery of nutrients and oxygen.^{25,27} Recent glycemic status, as measured by HbA1c, is inversely correlated with rate of wound healing.²⁸

Increasing age is associated with characteristic changes in the healing process that result in delayed healing. Delays have been documented in inflammatory response, collagen synthesis, and reepithelialization, along with decreased turnover and remodeling.^{29–31} Much of this change has been linked to changes in sex hormones. Wounds in elderly individuals have altered expression of estrogen-regulated genes and improvement in wound healing is seen with estrogen supplementation in both aged men and women.^{32,33}

Other patient factors that can impair wound healing include cigarette smoking and steroid use (Table 2-3). Cigarette smoking has a major negative impact on wound healing across all demographics, with two pack per day smokers having a six times greater risk of skin graft necrosis than nonsmokers.³⁴ Nicotine decreases proliferation of fibroblasts, macrophages, and endothelial cells and decreases tissue oxygenation.³⁵ Taking systemic glucocorticoid steroids negatively impacts wound healing by decreasing the necessary inflammatory response and decreasing fibroblast response. Wounds heal with incomplete granulation tissue and less contracture.³⁶

Table 2-3. Factors Affecting Wound Healing

Risk Factor	Mechanism
Obesity	Decreased perfusion of adipose tissue and increased inflammation
Malnutrition	Amino acid, vitamin, mineral, and cofactor unavailability
Diabetes	Pathologic inflammation and decreased migration
Age	Decreased estrogen levels
Cigarette smoking	Decreased tissue oxygenation
Steroid use	Decreased inflammatory and fibroblast response

Complicated wound healing

Chronic wounds. Wounds are considered chronic when they fail to heal for more than 42 days or exhibit frequent recurrence in the same location. These are most commonly seen in situations with multiple systemic risk factors for wound healing. Approximately 90% are either pressure ulcers, venous ulcers, or diabetic ulcers, though an estimated 20% of acute wounds with significant tissue loss transition into a chronic pattern, so clinicians working with surgical wounds should be aware of the behavior associated with chronic wounds.^{37,38} Histologically, chronic wounds are associated with increased presence of inflammatory cells and inadequate extracellular matrix formation.³⁹ Derangements in moisture balance, bacterial burden, and perfusion are all implicated in pathogenesis. Exudate from chronic wound shows increased proteolytic activity, degrading growth signals and ECM components.^{40,41} As chronic wounds progress, bacterial burden and necrotic tissue burden increase, stimulating further inflammatory signaling. Significant tissue edema is often present, decreasing perfusion and inhibiting wound healing.³⁷

Keloid scarring. Keloid scars arise when the proliferative phase of wound healing is prolonged, without appropriate negative feedback and remodeling. These scars grow outside the initial margin of the wound, can become large, and are often associated with pain, pressure, and pruritus. They do not spontaneously regress. Histologically, these have few organized

bundles of collagen, with unorganized deposition of both collagen type I and type III.^{42,43} The likelihood of a patient forming keloid scars after wounding appears to have a strong genetic contribution and is particularly enriched within the African American population.^{44,45} The altered pathophysiology underlying keloid scarring centers on overactivation of fibroblasts in the proliferative stage. This is thought to be mediated by TGF- β and PDGF signaling,^{46,47} as well as increased VEGF signaling from keratinocytes overlying the scar.^{48,49} Recent work shows increased fibroblast activation and inflammation may also be due to the effects of tension on a healing wound, mediated by fibroblast focal adhesion kinase (FAK) mechanotransduction.⁵⁰

CLINICAL IMPLICATIONS

While many factors affecting healing may be out of the surgeon's control at the time of a procedure, a clinician can have a large impact on healing outcome through appropriate wound care including closure design and tension minimization, management of bacterial burden, wound dressing, and monitoring. The proper choices for each of these parameters depend largely on the type and location of the initial wound.

Wound closure

The main types of closure used in dermatologic surgery are primary closure and closure by secondary intention. For primary closure, the dermis is approximated immediately after a procedure. For closure by secondary intention, a wound is left open to heal spontaneously. Delayed primary closure refers to leaving a wound open for initial care and approximating the dermal edges at a later time.

Primary closure utilizing sutures, staples, or surgical glue is the first choice for wounds that are clean and have sufficient tissue for approximation. For these wounds, the processes of reepithelialization and wound contracture are less necessary for healing. This method often requires the least complex wound care, and heals more quickly and with less pain. Wounds closed in this manner have reduced scarring.⁵¹

Closure by secondary intention is appropriate for most wounds that do not meet criteria for primary closure or grafting, such as contaminated wounds or those with significant tissue destruction, or in cases where shallow wounds would be expected to heal fairly quickly. This process often requires more involved care during the healing process. While it is generally thought that healing by secondary intention is more likely to leave a prominent scar, cosmetically favorable healing through secondary intention has been reported in many instances, particularly on concave body surfaces such as the nasolabial fold, canthus, ears, and temples.^{51,52}

Hemostasis

Hemostasis is essential for wound healing, as the activation of the coagulation cascade and formation of a clot play an essential role in initiating the healing cascade. While hemostasis is an important goal at the end of surgery, some bleeding at the time of dressing and wound care is frequently seen. The main options for hemostasis in open or actively bleeding small wounds are caustic agents, physical agents, and physiological agents. Caustic agents include aluminum chloride, ferric sulfate, silver nitrate, and zinc chloride. These work by local tissue destruction, initiating coagulation and forming a small eschar. Aluminum chloride is most commonly used, and is desirable because it does not leave residual skin pigmentation. Noncaustic agents include physical agents, gelatin, cellulose, p-GlcNAc, and microfibrillar collagen, which promote clot formation by forming a mesh for further clotting. These approaches may promote a granulomatous foreign-body reaction so they should be avoided in settings of infection, or near the eyes in particular. Physiological agents include epinephrine and cocaine, which induce vasoconstriction, as well as topical thrombin, fibrin sealant, or platelet gels.⁵³

Management of bacterial burden

SSIs are generally uncommon in dermatologic surgery, and their frequency can range from 3% to 28% depending on the body site involved. SSIs are more frequently seen in the distal lower extremities.⁵⁴ The most commonly isolated organism in SSIs is *Staphylococcus aureus*, much of which is from

an endogenous origin.⁵⁵ The skin resident *Staphylococcus epidermidis* can also lead to pathogenic infection when it adopts different virulence factors.⁵⁶ Though less common, wound infections with gram-negative bacteria and *beta-hemolytic streptococci* are observed, often in the lower extremities, and can be particularly destructive.

The majority of dermatologic surgeries do not require systemic antibiotic prophylaxis unless the wound appears dirty or the patient has a particularly high risk for infection.⁵⁷ If prophylaxis is desired because of patient risk factors or wound location, a single preoperative dose is recommended. If the wound does appear infected or dirty, a 7- to 10-day course of systemic antibiotics is merited. Antibiotics should be chosen based on suspected pathogen.⁵⁷ Antibiotic choices and protocols are discussed in detail in [Chapter 7](#).

If a wound appears heavily contaminated or has a large burden of devitalized tissue that may serve as a nidus for infection, it is important to remove as much of this as possible by debriding the wound before dressing. There are multiple options for debridement. The first-line option, sharp debridement, involves use of instruments to remove material with local anesthetic. It is most effective and targeted, but can be painful and is not always well tolerated. Other options include autolytic debridement, in which a moist environment is created to facilitate digestion of necrotic tissue by endogenous enzymes, or enzymatic debridement using laboratory-produced collagenase or papain. Autolytic debridement carries a risk of overhydration and maceration, while enzymatic debridement is expensive and thus not a first-line choice. Surgical debridement under anesthesia may be performed as well, while recently other options, such as cold helium plasma with radiofrequency, have been explored as well.⁵⁸ Hydrosurgery offers a less damaging option in which a saline beam is applied tangentially to the wound, but also requires anesthesia and is not widely available.⁵⁹

Wound dressings

Once hemostasis is achieved and bacterial burden is managed, the clinician must decide whether to dress a wound, and, if dressing is desired, what type to use. Dressings can serve multiple functions including protection, hemostasis, compression, and moisture regulation. However, the time spent

changing dressings and cost of advanced dressings must be weighed against their benefit in each circumstance. For acute surgical wounds closed by primary intention without infection or excess exudate, there is no evidence that use of a dressing or choice of specific dressing has an impact on time of healing, prevention of infection, pain, or scarring.⁶⁰ Given the role of tension in scarring and fibrosis, novel dressings, which externally reduce tension, may show potential for decreasing scarring, though these benefits may be nonexistent if a wound is well sutured with minimal tension.⁶¹ Cost and ease of use should always be considered when deciding on dressing choice.

For wounds healing by secondary intention, the level of bacterial burden, amount of exudate, and patient preference guide dressing choice. Dressings vary based on degree of occlusion, permeability/moisture, absorption, adherence, compression, and maintenance involved.

Antimicrobial dressings

The use of local antimicrobials following a procedure is not recommended for general prevention of SSIs. They are no more effective at preventing SSIs than petroleum, and topical antibiotics can increase the frequency of resistant organisms within a wound.^{62,63} If a local antimicrobial is desired due to risk of local infection, iodine- or silver-based solutions or dressings are often chosen because they provide broad coverage and are associated with lower levels of bacterial resistance than topical antibiotic ointments. Iodine-based options include povidone-iodine, available as an impregnated tulle, or cadexomer iodine, a starch which absorbs fluid while slowly releasing iodine, and is useful for exudative wounds. These should not be used in patients with thyroid conditions due to low levels of systemic absorption. Silver-based antimicrobials are available as a topical cream (silver sulfadiazine) or impregnated in a variety of dressings, including foam, gauze, and nanocrystalline preparations for slow release. Silver sulfadiazine cream is less favorable for use in most settings because it stains skin and forms a pseudo-eschar. Specific silver-impregnated dressings should be chosen based on other desired dressing properties (Fig. 2-2). On a practical level, many dermatologic surgeons utilize mupirocin ointment as an antibacterial ointment of choice, though contact allergy and even anaphylaxis have been reported.

Figure 2-2. Silver and absorbent foam dressing for exudative wound in high-pressure region. (A) The wound is covered with nonadherent, silver-impregnated dressing. (B) The silver dressing is covered in occlusive foam layer for padding and absorption. (C) The layers of dressing are secured with adhesive.

Occlusive dressings

Given the importance of maintaining a moist and relatively sterile environment for healing, occlusive dressings are the first choice for noninfected, nonischemic wounds. These dressings maintain a moist environment preventing drying and eschar formation, which are detrimental for reepithelialization. As compared to basic gauze dressings, occlusive dressings increase reepithelialization and collagenization and decrease rates of SSIs.^{19,64,65} Occlusive dressings range widely in their indications, degree of permeability to air and water, level of fluid absorbency and adherence (Table 2-4).

Table 2-4. Types and Properties of Occlusive Dressings

Type	Characteristics	Advantages	Disadvantages	Indications	Maintenance
Hydrogels	Semipermeable, nonadherent	Pain relief, nontraumatic removal, allows autolytic debridement	Risk of infection, may overhydrate	Dry, painful wounds	Change every 1–3 days
Polymer films	Transparent, Semiocclusive, adherent	Protects from infection	Fluid trapping, can strip skin	Wounds with little exudate, closed wounds	Leave in place 7 days or until fluid leaks
Hydrocolloids	Opaque, impermeable, adherent, absorbent, occlusive	Protects from infection, allows autolytic debridement	Malodorous discharge, fluid trapping/can overhydrate	Low exudate	Leave in place 7 days or until fluid leaks
Polymer foams	Opaque, absorbent, occlusive, nonadherent	Cut to shape, thermal insulation	Can be incorporated into wound if dry	Light to moderate exudate, sloughy wounds	Must change every 3 days or incorporated into wound
Alginates	Nonadherent, highly absorbent, hemostatic	Helpful in hemostasis	Malodorous	Wounds with heavy exudate or moderate bleeding	Change when soaked in exudate

Polymer films such as Tegaderm and Opsite, represent the classic occlusive dressings. These adhere to healthy skin, but not to the wound site. They are semipermeable, allowing air and water vapor exchange, and they are clear, allowing visual monitoring of the wound. These provide no cushioning or absorbency so they are appropriate for shallow wounds with low exudate only, such as those seen in most surgical site repairs. **Polymer foams**, such as Allevyn and Lyofoam, consist of an absorbent surface in contact with a semipermeable backing to prevent leakage. These are appropriate for heavily exudative wounds. They are nonadherent and require another layer of dressing (Fig. 2-2B). **Hydrocolloids**, including Exuderm, Duoderm, and Comfeel, consist of multiple layers. When placed on a wound, the bottom layer forms a gel. This moisturizes the wound bed, promoting autolytic debridement. The top layer is adherent and virtually impermeable, providing protection to the wound during daily activity. **Hydrogels**, such as Restore-hydrogel, SAF-Gel and CuraGel, consist of a matrix of insoluble polymers and water, allowing them to both donate moisture to a dry wound surface and absorb wound exudate. They are commonly used to promote autolytic debridement. **Alginates**, including Sorbsan and Kaltostat, are produced from salts of alginic acid found in brown seaweed. These dressings partially dissolve upon contact with a wound bed when sodium ions from the wound are exchanged with calcium ions from the dressing, forming a highly absorptive gel appropriate for wounds with high levels of exudate (Fig. 2-3).

Figure 2-3. Alginate dressing for bleeding, exudative wound. (A) Alginate dressing is applied and binds to wound site. (B) Adherent gauze is used to secure and protect alginate.

Specific indications and restrictions of each type of occlusive dressing are detailed further in [Table 2-5](#).

Table 2-5. Dressing Choice Based on Wound Characteristics

Wound Characteristics	Dressings to Consider
<i>Primarily closed</i>	Polymer film or petroleum
<i>Dry, necrotic</i>	Hydrogel or hydrocolloid, debride when hydrated
<i>Sloughing</i>	Debridement, cadexomer iodine or silver-based dressing
Shallow	Hydrocolloid
With exudate	Alginate
<i>Deep, nongranulating</i>	Synthetic dermal matrix or bilayer
<i>Red, granulating</i>	
Wounds with deep sinuses	Alginate ribbon or hydrogel
Deep cavity	Foam, foam in plastic pouch
Shallow, heavy exudate	Alginate sheet
Shallow mild exudate	Foam
Shallow nonexudative	Hydrocolloid
<i>Pink, epithelializing</i>	
Heavy exudate	Alginate
Mild exudate	Hydrocolloid
Nonexudative	Film
<i>Infected</i>	
Heavy exudate	Negative-pressure wound therapy, hydroconductive dressing
Mild exudate	Silver or iodine based dressing
<i>Edematous</i>	Compressive dressing
<i>Ischemic</i>	Hyperbaric oxygen therapy

Absorptive dressing

While research favors dressings that maintain local moisture in most settings, absorptive dressings are indicated in settings where excessive exudate is

problematic, such as primarily closed wounds with excess drainage or chronic wounds in which exudate can be destructive. While gauze is the classic absorptive dressing, it has been shown to be a poor barrier against bacteria, and it is frequently incorporated into wound beds, disrupting formation of granulation tissue when removed.⁶⁶ Recent alternatives include the layered hydroconductive dressings, in which a bottom layer wicks moisture out of the wound bed (Fig. 2-4). These dressings are effective at removing both moisture and debris, contributing to a reduced bioburden in contaminated wounds.⁶⁷

Figure 2-4. Hydroconductive dressing for exudative wound. (A) Following debridement, hydroconductive dressing is applied over wound bed. (B) An abdominal pad is applied over dressing for additional absorption and padding. (C) Dressing is secured in place.

Compressive dressing

Dressings that provide compression are useful when edema prevents healing. Though most studies of compression have focused on chronic wounds, edema also interferes with healing of acute surgical wounds, most commonly those

in the lower extremities. The benefits of compressive dressing have been demonstrated for acute healing of excisional wounds in the lower extremities healing by secondary intention.⁶⁸ The classical compression dressing is the Unna wrap, a zinc oxide compression dressing. However, this dressing can be uncomfortable and restrict motion. Over the past decade, multiple commercial alternatives have arisen providing varying levels of customization that have been shown to be equally effective to the Unna wrap in promoting healing, though can require training for patients to manage (Figs. 2-5 and 2-6).^{19,69}

Figure 2-5. Tubular elastic compression to promote healing of lower extremity wound. (A) After wound is dressed and covered, tubular elastic is applied. (B) Elastic extends up to knee level.

Figure 2-6. Absorptive dressing and two-step elastic compression for exudative wound in edematous leg. (A) Exudative wound is wrapped in hydroconductive dressing for absorption of exudate. (B) First layer of Coban™ 2-layer elastic dressing is applied over dressing. (C) Second layer of Coban™ 2-layer elastic dressing is applied and secured.

Wound-healing adjuncts

For many acute surgical wounds, achieving hemostasis, managing bacterial burden, appropriate closure, and dressing will be sufficient to achieve a favorable healing outcome. However, up to 20% of acute surgical wounds with significant tissue loss become chronic, and this is more likely when working with patients whose physiology is not optimal for healing.³⁸ When working with a wound with a low likelihood of healing, incorporating additional healing adjuncts can have significant benefits. These include the use of synthetic skin substitutes, negative-pressure therapy, hyperbaric oxygen therapy, and synthetic growth factors to promote wound closure in the acute period.

Synthetic skin substitutes

Because of the difficulties obtaining sufficient tissue for autologous grafts, synthetic alternatives have been developed to close large wounds without requiring living tissue transplantation. Synthetics can be cellular or acellular and can be single layer (dermal or epidermal) or bilayer. Single-layer synthetic epidermal grafts generally consist of autologous keratinocytes expanded in culture, which are laid over a wound bed to reepithelize and provide protection, usually as a local specialized service to select burn hospitals. This process is time consuming and the effective uptake of these grafts varies widely. Currently, an entire body surface area worth of epidermis can be grown from a 3 cm² biopsy, and novel methods of delivery of allogeneic cells, ranging from impregnated matrices to aerosolized cells, are in development to improve incorporation.^{70,71}

For wounds that have significant loss of dermal matrix, synthetics involving dermal substitutes can provide a matrix for cellular migration/growth. These matrices allow infiltration of fibroblasts, angiogenesis, and eventually can provide a scaffold for reepithelialization. The most common of these are collagen-based dressings. These can be decellularized bovine or laboratory-generated matrices, or solubilized collagen repolymerized into fibers, films, or sponges. Cellular alternatives, such as Dermagraft, consist of neonatal fibroblasts cultured on a bioabsorbable mesh to synthesize a physiologic dermis. These are more effective at stimulating a healing response than acellular layers and have outcomes comparable to allograft.^{72,73} These matrices promote hemostasis and fibroblast proliferation and can provide a base for reepithelialization, though they do not offer the protection of an epidermal layer.

Other physiological skin substitutes consist of bilayered scaffolds, which can be acellular or cellular. With Integra, an acellular bilayer system, a silicone epidermal substitute is initially placed over an artificial dermal collagen matrix. After the dermal matrix is infiltrated and vascularized, the silicone layer is removed and replaced with epidermal grafts.⁷⁴ This system has favorable reconstructive and cosmetic outcomes, often with greater patient satisfaction than autologous grafting.⁷⁵ Apligraf, a cellular bilayer, consists of neonatal keratinocytes and fibroblasts grown on a bovine collagen matrix. It decreases healing times when used as an adjunct to autografts or alone on chronic wounds,^{76,77} though it has a very short shelf life and its significant expense may limit its use.

Negative-pressure therapy

For wounds healing by secondary intention or delayed primary closure for which excessive exudate, infection, or inflammation inhibit healing, negative-pressure therapy is an option for management. These systems apply negative-pressure suction through a sealed wound dressing by way of a pump. These pumps can be large and stationary for inpatient use or small and portable for long-term outpatient use. The use of negative pressure significantly decreases edema and exudate and stimulates both fibroblast migration and contraction.^{78,79} This method has been clearly established to improve outcomes in chronic wounds⁸⁰; however, the benefit is less clear for acute wounds healing by secondary intention or delayed primary closure.^{81,82} This should be considered in acute wounds with a large amount of exudate to promote healing by secondary intention or prepare for delayed primary closure.

Hyperbaric oxygen therapy

Hyperbaric oxygen therapy involves delivery of 100% oxygen at a pressure above one atmosphere to the wound site. This is performed using hyperbaric oxygen chambers and is dependent on availability of chambers. It has been shown to significantly increase the amount of oxygen available to skin and promote wound healing, particularly in settings where healing is impaired by poor local blood supply or damage to the vasculature, as seen in chronic venous or diabetic ulcers.⁸³ While less widely used, this therapy significantly increases uptake of split-thickness grafts, uptake of compromised flaps, healing of previously irradiated tissue, and healing of acute wounds such as burns and crush injuries therapy.⁸⁴ If available, this should be considered if oxygenation is a limiting factor in healing of an acute wound.

Long-term monitoring

Most dermatologic surgery wounds will be followed in the outpatient setting; therefore, instructing patients in proper wound care is essential for optimal healing. Patients with wounds closed primarily should not shower for the first 48 hours, and avoid baths or showers greater than 10 minutes throughout

healing. Patients with wounds requiring complex dressing should cover dressings with a water impermeable barrier during bathing. Patients with superficial wounds should avoid direct UV exposure to the wound during healing, because exposure may increase the risk of hyperpigmentation.⁸⁵

Throughout the healing process, clinicians should monitor for evidence of nascent infection and wound dehiscence. If signs of acute infection such as increased purulent discharge, erythema, or warmth are present, wounds should be swabbed and cultured. Empiric topical or systemic antibiotics should be initiated, and mechanical, surgical, or autolytic debridement should be performed based on the extent of infection. If superficial wound dehiscence develops in a primarily closed surgical wound, debridement of necrotic tissue should be performed. Following this, wounds with only superficial dehiscence can be left to close by secondary intention, while those with larger dehiscence should be addressed with negative pressure dressing or tension-relieving approaches such as tape, glue, or sutures.⁸⁶

CONCLUSIONS

Wound care and dressing choice play an important role in dermatologic surgery, because even the best-designed closure can be undone by less-than-optimal wound care. Patient education is of paramount importance, because even a fully healed wound will only retain 80% of the tensile strength of its preinjury period. Wound dressing choice following an uncomplicated surgical procedure should be kept as straightforward as possible. For sutured wounds repaired with absorbable sutures alone, using a simple polymer film dressing may allow the patient to return quickly to his or her normal activities and concomitantly minimize the need for re-dressing at home.

Acknowledgments. We greatly appreciate Cindy Shephard, Kelly Carnaggio, and Maureen Clark for their expert guidance and instruction.

CHAPTER 3 Preoperative Evaluation, Patient Preparation, and Informed Consent

Dori Goldberg
Amanda Auerbach
James Bota
Mary E. Maloney

SUMMARY

- Preoperative preparation should include a discussion regarding the procedure; a review of the patient's history, medications, and allergies; any appropriate physical examination; obtaining informed consent through a process; and answering patient and/or family questions.
- The preoperative evaluation ultimately serves as a forum to assess probability of overall success and cement the patient–physician relationship.

Beginner Pearls

- From the first moment the patient steps into the office, the front office staff has the opportunity to begin collecting information, such as the patient's mood and degree of anxiety.
- If capacity is ever in question, simple questions like “where do you live?” or “how did you get here?” are innocuous queries that evaluate mental status without prompting any perceived stigmatization.

Expert Pearls

- Outline postoperative restrictions ahead of the procedure so that patients avoid conflicts with athletic events as well as allowing them to make any arrangements they may need for home care, child care, time off from work, or transportation to and from the procedure.
- Patient preparation and the informed consent process is a critical part of the surgical procedure.

Don't Forget!

- While a written signature is desirable, the real goal of the consent process is effective communication.
- If an informational packet is provided to help patients prepare, it may include an outline helping them prepare for the pre- and postoperative period.

Pitfalls and Cautions

- Patients who have many questions or voice cosmetic concerns when they are scheduling their procedure are self-identifying as individuals who would benefit from an in-office preoperative consultation.

Patient Education Points

- Without adequate preparation, even mild and expected outcomes, such as edema and ecchymoses, can be a cause for significant concern.
- Make the patient your partner, and use partnering language when discussing the surgical plan.
- Certain subtleties become evident over time, such as personality, forgetfulness, unrealistic expectations, or specific fears that can be noted by the staff and guide the remainder of the visit. These observations can be acted upon early and preemptively, helping to tailor the patient care experience in a positive fashion.
- Some patients under 18 may look older than they are (and vice versa), so it is important when operating on young adults to check their date of birth.
- A full discussion of benefits and risks improves mutual trust and respect between the physician and patient, and ultimately improves patient satisfaction.

CHAPTER 3 Preoperative Evaluation, Patient Preparation, and Informed Consent

INTRODUCTION

Evaluating the patient preoperatively, preparing them for surgery, and going through the informed consent process are important prerequisites that must be accomplished prior to initiating dermatologic surgery. This is important from an ethical standpoint, but also ultimately yields significant time savings for the surgeon, as an informed patient ultimately is less likely to make repeated telephone calls or return visits to the office in the postoperative period. Discussing procedural risks and the possible need for additional surgery or procedures in the postoperative period is always wise, as forewarning and educating patients creates a team atmosphere that ultimately pays significant dividends.

PREOPERATIVE EVALUATION

The preoperative evaluation is most simply thought of as an evaluation of the physical, medical, and emotional preparedness of the patient for a selected procedure. This formal evaluation is generally a multifaceted discussion regarding the procedure; a review of the patient's history, medications, and allergies; any appropriate physical examination; obtaining informed consent through a process; and answering patient and/or family questions. The

evaluation can be performed up to several weeks in advance of the surgery, though it may also take place on the same day of the procedure. If a same-day evaluation is chosen, the physician must be prepared to cancel the procedure if it is discovered the operation scheduled is inappropriate for the lesion, or the patient is not a good surgical candidate for medical or psychological reasons. There are many factors that should be taken into account when deciding upon the timing of this evaluation including office setup, physician preference, patient mobility, and travel distance. Nevertheless, the preoperative evaluation ultimately serves as a forum to assess probability of overall success and cement the patient–physician relationship.

Team care is a critical component of the preoperative evaluation. It begins with the very first patient contact and continues up to the initiation of the procedure itself. All members of the team should be empowered and encouraged to have input in this evaluation and have the authority to halt it for any concerns. From the first moment the patient steps into the office, the front office staff has the opportunity to begin collecting information, such as the patient’s mood and degree of anxiety. The medical assistants and nursing staff carry this process forward, with obtaining a history, complete medication list, and any other standard data points necessary for the field of practice.

Certain subtleties become evident over time, such as personality, forgetfulness, unrealistic expectations, or specific fears that can be noted by the staff and guide the remainder of the visit. These observations can be acted upon early and preemptively, helping to tailor the patient care experience in a positive fashion. Moreover, these initial encounters should serve as a filter for red flags like abnormal labs or vital signs, concerning new symptoms, or patient aggression/combativeness. Safety is the responsibility of the team, and the surgeon, as team leader, must use all information gathered to determine the safest way forward. Overall, the guiding principle is that every person of the care team plays an essential role in the overall patient evaluation and experience. [Table 3-1](#) is a summary of possible reasons for delaying a procedure.

Table 3-1. Reasons to Delay Surgery

Psychological

1. Evidence of medication or drug use that impairs judgment
2. Unavailability of health care proxy or guardian when patient is incompetent
3. Indication that the patient does not understand the procedure (negating informed consent)
4. Unrealistic expectations
5. Hostility/anger
6. Evidence of alcohol ingestion/intoxication

Physical Examination

1. Unstable medical condition
 - a. Extreme hypertension
 - b. New or symptomatic cardiac arrhythmia
2. Fever
3. Acute illness
4. Angina/unstable angina
5. Infection/cellulitis of biopsy site
6. Suggestion of boney involvement

Laboratory Examination

1. INR >3.5
2. Thrombocytopenia
3. Metabolic involvement
4. Hypoxia

Miscellaneous

1. Pathology and clinical evaluation do not match
2. Unaccompanied minor without a pre-signed consent form

Patient capacity

Establishing patient decision-making capacity is a cornerstone of the informed consent process and the overall preoperative evaluation. Obtaining an adequate history and providing postoperative instructions is not possible without a patient's ability to accurately understand and make medical decisions on their own behalf. For the vast majority of patients, this is not a problem, but for a few patients, the ability to understand is a significant and delicate issue. Culturally, a stigma is often associated with mental incompetence, and questioning an elderly patient's abilities can interfere with rapport, potentially making them angry or defensive. Furthermore, those with functional impairments may hide their diminished capacity well. It is important to understand that competence is a legal term, which is commonly confused with capacity—a physician assessment. For informed consent, a patient must be capable of understanding the procedure and relevant information, making a rational choice, and understanding any potential complications or consequences. A patient's family can provide significant insight into capacity and/or competency status. Oftentimes, the family may be quick to provide information that the patient requires a co-signer or legal guardian present for paperwork, which makes the process straightforward. The dynamics between the patient and their family may also hint at capacity; repeating instructions in different wording, family leading the conversation, and visible frustration may be cues that suggest the need for a more thorough mental status examination. If unaccompanied, the physician should pay close attention to the patient's general hygiene, coordination, and speech patterns. If ever in question, simple questions like "where do you live?" or "how did you get here?" are innocuous queries that evaluate mental status without prompting any perceived stigmatization.

During the initial evaluation, it is important for all members of the team to quickly assess the patient's overall state of mind. Are they anxious? Confident? Overly worried about cosmetic appearance? With this information, the best support can be offered by the team. Indeed, adequate psychological support cannot be overemphasized for a smooth and successful outcome.

Of course, minors cannot provide true consent for any procedure, though their assent is important. Some patients under 18 may look older than they are (and vice versa), so it is important when operating on young adults to check their date of birth. Be sure any child's parent or legal guardian gives the

consent. This can generally be performed with a phone consent as long as it is witnessed by having a staff member join on the phone to verify the consent.

HISTORY REVIEW

A standard review of medications, allergies, and past medical history must be obtained for every preoperative evaluation. In particular, the presence of a pacemaker, defibrillator, or the use of anticoagulation may impact surgical decision making and techniques, including the type of electrosurgery used, the type of closure chosen, or the type of dressing applied. A history of smoking portends poor wound healing, making a large flap or graft less desirable due to higher risk of failure. A history of alcohol or other substance abuse carries risks of poor wound healing, bleeding, and possible poor compliance with postoperative instructions. A history of radiation treatment to the surgical area increases risks of poor wound healing and tissue mobility. Any positive history should best be shared with the entire team for planning and implementation of the safest care.

Physical examination

Vital signs, including blood pressure, pulse, and respiration rate, are sometimes performed prior to procedures, though doing so is not a standard of care for outpatient dermatologic surgery procedures. Elevated blood pressure is common preprocedurally, and oftentimes is secondary to anxiety or exertion. Repeat measurements are imperative to better delineate “white coat hypertension” or exertional hypertension from more ominous conditions such as hypertensive urgency or emergency. Often, patients may abstain from their antihypertensive medications prior to surgery under the misconception that these are anticoagulants. If the patient has their medication with them, the physician may consider having them take their scheduled dose and re-evaluating after 15 to 20 minutes. Hypertensive urgency is defined as blood pressure >180 mm Hg systolic and >120 mm Hg diastolic in the absence of an acute stressor. A careful review of systems for end-organ damage is necessary, and consideration of procedure abortion and referral to the emergency department is paramount.

Pulse must be evaluated for rate and regularity. Arrhythmias, like atrial fibrillation, are not uncommon in those on anticoagulants, and a determination of whether such an arrhythmia is well controlled must be made prior to surgery. New or symptomatic arrhythmia is a cause for abortion of the procedure and referral to the emergency department.

Any patient showing outward signs of other concerning and acute medical processes, such as shortness of breath, chest pain, or acute neurologic deficit, should be referred to the ED immediately.

PATIENT PREPARATION FOR SURGERY

Cognitively preparing patients for surgery helps create a more positive experience for both patient and surgeon. This preparation includes elements of informed consent, but extends beyond the legal requirements to include patient education about all elements of the procedure from the preoperative to postoperative periods.

Preoperative consultation is one option for cognitively preparing patients for surgery. A clinic visit allows the patient to meet their surgeon in advance and discuss all elements of the procedure in detail ahead of time. This is particularly beneficial for planning very complex surgical procedures, or with anxious patients or patients having surgery for the first time. When the patient is a child or developmentally delayed adult, preoperative consultation with both the patient and parent or legal guardian present allows proper selection of anesthesia. After a full discussion of the procedure, both the surgeon and parent/guardian determine whether local infiltrative anesthesia alone is appropriate, or whether the addition of a topical anesthetic, an oral anxiolytic, sedation, or general anesthesia is required to safely and comfortably perform the necessary procedure. This discussion is often helpful for extremely anxious patients as well, who may benefit from an oral anxiolytic such as lorazepam. Obtaining informed consent at the time of preoperative consultation allows the patient to take an anxiolytic prior to surgery, significantly improving the anxious patient's surgical experience. Patients taking anxiolytics should be directed to have someone drive them to and from their surgery. Such preoperative consultations can occur by telephone if in person consultation is not feasible.

Providing patients with an informational packet either by mail or e-mail is a simple and effective way to review the most important elements of surgery. Outlining any restrictions on activities (bending, lifting, housework, sports) as well as the likely duration of these restrictions ahead of time may help patients avoid conflicts with athletic events as well as allowing them to make any arrangements they may need for home care, child care, time off from work, or transportation to and from the procedure. The potential timing for follow-up visits should be mentioned as well to prevent patients from scheduling surgery immediately before leaving on a trip (unless proper follow-up can be arranged with another provider or is not needed).

If an informational packet is provided to help patients prepare, it may include an outline helping them prepare for the pre- and postoperative period.

During the preoperative consultation, or immediately preceding surgery, a full discussion of the proposed procedure, including the risks and benefits, should be discussed. This is largely part of the informed consent process, and is critical in preparing a patient for their surgery. Reviewing all other reasonable treatment alternatives and the risks and benefits of these treatment options will help patients identify the best option for them.

Once the treatment modality has been selected, the patient will be best prepared if they are walked through the procedure starting with a description of how they will be positioned, how the site will be prepped and draped, and the use of anesthesia. If an excisional procedure such as an excision or Mohs surgery is planned, discussion of possible closures (secondary intention, linear closure, flap or graft, or two-staged closure, if this is anticipated) and potential shape and length of the scar line can be reviewed at this time. Patients are often very concerned about how “long” their scar will be. This is an excellent opportunity to educate patients about the cosmetic principles utilized in designing linear excisions, flaps, and grafts, and discussing the role of hiding incision and scar lines within relaxed skin tension lines and cosmetic boundaries. Understanding that the length of the incision is far less important than the contour and placement of the incision lines, and the preservation of symmetry and free margins, helps both prepare the patient for surgery and instill confidence that their surgeon has expertise in the area of wound reconstruction. In a procedure such as Mohs surgery, where the degree of needed reconstruction cannot always be predicted ahead of time,

patients should be informed of possible closures, and a more detailed discussion can be held at the time of reconstruction.

Sample educational handout outline for preoperative preparation

- Preparing for surgery
 - Avoid nonessential aspirin (patients should check with their PCP prior to stopping ASA)
 - Avoid ibuprofen and other NSAIDs for at least 24 hours before surgery if possible
 - No alcohol for 24 hours before surgery
- Detailed description of the surgery
 - For more complex procedures such as Mohs surgery, a very detailed description of the procedure can be included
- On the day of surgery
 - Shower/wash the surgical site with soap and water
 - Do not wear make-up or jewelry on or near the surgery site
 - Avoid perfume, avoid hair products if the surgical site is the scalp (many hair products are flammable when in contact with cautery)
 - Do not eat or drink anything after midnight, the night before (if going to the OR)
 - Take all of your regular medications (include any exceptions)
 - Inform patients what to bring with them (e.g., book, tablet device, friend, snacks), if this is permitted
- What to expect after surgery
 - Activity limitations
 - Alcohol, medication restrictions
 - Wound care instructions will be given after surgery
 - Follow-up
- Activity restrictions—it is often helpful to discuss this in front of a family member
- Wound care—instructions should be given orally and provided in writing with instructions on who to call with problems or concerns

- Follow-up—appointments should be scheduled if needed and it is helpful to inform patients if more than one visit will be needed
- Healing—preparing patients for what may occur postoperatively can eliminate anxiety and minimize phone calls. Discussing swelling, bruising, scarring, and the potential for scar revision upfront will help patients know what to expect as their wound heals
- Pain management
 - Ice, elevation
 - Recommended analgesics (e.g., acetaminophen, NSAIDs, narcotics) with timing and dosage recommendations
 - Elements that may be included when preparing patients
- Name of the hospital where the procedure is to take place
- Name of the specific procedure for which consent is being given (now commonly including location)
- Name of the practitioner performing the procedure
- Statement that the procedure, anticipated benefits, risks and alternatives were explained to the patient or their representative
- Signature of the patient or their representative

If the patient is interested in closure by another surgeon (plastic surgeon, oculoplastic surgeon, or other), this is often revealed during this discussion. This plan is ideally addressed during a preoperative consultation so that such arrangements can be coordinated in advance of the surgery. Patients who have many questions or voice cosmetic concerns when they are scheduling their procedure are self-identifying as individuals who would benefit from an in-office preoperative consultation. Seeing such patients ahead of time to discuss questions and concerns in detail will streamline the actual surgery day and alleviate patient and provider concerns.

Preparing patients for the postoperative period can begin during the preoperative consultation and extend through the end of the surgery. Patients, often nervous about their procedure, may not hear all instructions, and can benefit from repetition before and after surgery. Having a friend or family member present to hear instructions is ideal. If the patient is relaxed, reviewing instructions can often occur in part during the surgical procedure as well.

If there will be a pathology result, inform patients when this will be available and how they will receive the result (telephone call, e-mail, postcard, at the follow-up visit). It may be helpful to ask patients if they are comfortable receiving results over the phone and whether or not you can leave a message. It is important to have consent to leave a detailed message on voicemail or with a family member prior to doing so.

INFORMED CONSENT

Obtaining informed consent is one of the most important steps in the preoperative period. It establishes realistic patient expectations and creates a protective legal framework for the physician to operate within. Failure to inform patients adequately of the potential associated risks and expectations can be viewed as negligence, and performing a procedure on a patient without their express consent can be considered battery in a court of law, although witnessed verbal consent may be acceptable in some situations. The patient must be provided the information to adequately evaluate a procedure before agreeing to that procedure or surgery. The Joint Commission defines informed consent as agreement or permission accompanied by full notice about the care, treatment, or service that is the subject of the consent.¹

Before consent can be obtained, the physician must determine whether or not the patient has decision-making capacity. The patient must be over the age of 18 and mentally able to grasp the concepts presented. It is necessary to obtain consent from the health care proxy or guardian of mentally incompetent patients. There are many other potential barriers to patient understanding, including ineffective provider communication; lack of patient-provider shared decision making; lack of health literacy; and cultural issues. The surgeon must be alert to signs of inadequate patient understanding. Simplification of the content, length, and language may help reduce these communication barriers. A qualified medical interpreter may be utilized for patients with hearing or visual impairments or limited English fluency, though other technology-based communication approaches may be used as well. Asking the patient to summarize the discussion and their decision can also help to highlight those who have failed to understand, and it is up to the physician to uncover the barrier to effective communication and correct it before the procedure is initiated.

Once the surgeon has established the patient's competence, they may move on to detail the critical components of informed consent. These include an explanation of the proposed procedure in lay terms, an explanation of the reasonable standard of care, indications for the procedure, common adverse outcomes, unexpected adverse effects, and treatment alternatives, including the expected consequences of no treatment.

Risks to be discussed should include those that either a reasonable physician would disclose or a reasonable patient would think necessary to make an intelligent decision. This means that extremely rare risks need not be discussed, though these standards leave much ambiguity. The surgeon should review the likelihood of those risks based on available clinical evidence and their judgment. Risks addressed should include common adverse events (which may be mild), as well as those that are unlikely but severe. The patient should have the opportunity to refuse the procedure if they deem any of those risks intolerable.

For cases in which residents or fellows in training are participating, the attending physician should explain who will be performing the procedure. Patients should be informed that physicians in training will be performing portions of the procedure commensurate with the ability of the resident or fellow, and will be under the supervision of the teaching physician. Whether or not the supervising physician will be present during all portions of the procedure should be explained, as this may vary based on the level of competence of the trainee.

While a written signature is required, the real goal of the consent process is effective communication. Inadequate communication was found to be the root cause of the majority of unmet expectations and/or complaints reported to the Joint Commission.¹ Technically, informed consent does not need to be written, but without written documentation, it is difficult to prove the patient's agreement in a court of law. It is generally agreed that a written consent form should be placed into the patient's medical record prior to the procedure. The one exception to this practice would be in an emergent life-threatening condition requiring immediate surgery, in which the principle of implied consent is invoked.

In 2007, the Centers for Medicare and Medicaid Services proposed updated guidelines for participating practitioners obtaining consent.² Under these guidelines, consent must be a written document in the patient's medical

record and must include additional details, such as the name of the surgeon and a reference to the risks, benefits, and alternatives.

CONCLUSIONS

Patient preparation and the informed consent process is a critical part of the surgical procedure. Without adequate preparation, even mild and expected outcomes, such as edema and ecchymoses, can be a cause for significant concern. Working as a team with the patient, and appreciating that the patient is indeed the most important person in the room, helps guide appropriate decision making. A full discussion of benefits and risks improves mutual trust and respect between the physician and patient, and ultimately improves patient satisfaction.

CHAPTER 4 The Surgical Suite

Terrence A. Cronin, Jr.

SUMMARY

- A well-equipped, well-designed surgical suite improves the surgical experience for the patient as well as the dermatologic surgeon and maximizes patient safety.

- Dermatologic surgeons have historically operated in an array of surgical settings, including hospital operating rooms, outpatient ambulatory surgical centers (ASCs), and office-based surgical suites.
- The surgical suite or operating room needs to be well lit, well ventilated, and include ample floor space for an electric operating table, emergency equipment, Mayo stand(s), instrument storage, electrosurgical equipment, and sink.

Beginner Pearls

- Multiple electrical outlets in the surgical suite are very helpful.
- The surgical table should ideally be located at the center of the room. While a wider table may be more comfortable for larger patients, a narrow table allows the dermatologic surgeon to access the surgical site more easily and maintain good ergonomic posture.

Expert Pearls

- Eyeglass-mounted LED lights provide direct illumination for the surgical field and are increasingly becoming the norm as long-lasting battery packs coupled with a decreased price point make these the illumination technique of choice for many surgeons.

- Interior design features such as outdoor photographs, spacious rooms, and architectural window features providing more sunlight have positive effects on perceived anxiety and postoperative pain.
- Aesthetically pleasing healing environments can have a positive influence on patients, and many authors recommend the purposeful use of architecture, art, and music to improve the surgical experience for the patient.
- Since surgical rooms are often kept at a cooler temperature than other offices (given the heat generated by lighting, surgical gowns, and other equipment), for patients' comfort, extra blankets and pillows may be made available.

Don't Forget!

- Ergonomic approaches to minimizing injury risk for the surgeon include modifying footwear, flooring, surgical instruments, operating position, lighting, and table height.
- When designing and building a dermatologic surgery suite, it is important to consider future growth.

Pitfalls and Cautions

- Erring on the side of larger operating rooms with abundant storage permits future expansion and flexibility.
- State and federal laws govern medical waste disposal.
- Multiple surveys of Mohs surgeons found that over 90% of respondents experienced symptoms exacerbated by surgery including stiffness and pain of the neck, shoulders, and lower back, as well as headaches.

CHAPTER 4 The Surgical Suite

INTRODUCTION

Dermatologic surgery encompasses a broad range of procedural complexity, from standard procedures such as biopsies, electrosurgery, sclerotherapy, soft-tissue augmentation, and toxin/filler injections to more aggressive surgical procedures such as skin cancer excisions, Mohs surgery, complex reconstruction, laser resurfacing, liposuction, and hair restoration.

It is important that the dermatologist practice with skill in a well-equipped, well-designed surgical suite that improves the surgical experience for the patient as well as the dermatologic surgeon, and—most importantly—maximizes patient safety. Dermatologic surgeons have historically operated in an array of surgical settings, including hospital operating rooms, outpatient ambulatory surgical centers (ASCs), and office-based surgical suites.^{1,2} Any office-based surgical facility should ideally be organized into separate rooms providing reception, laboratory, and the surgical suite.

The ASC tends to be a sophisticated extension of the dermatologic surgery practice in which the ASC is a separate defined entity within a larger medical office. Specific requirements for ASCs vary from state to state, and therefore will not be addressed in detail. In general, facility fee reimbursement from third-party payers requires state licensure and Medicare certification.¹

The dermatologic surgeon needs a large dedicated room to operate comfortably, whether standing or sitting, along a 360-degree circumference around the patient.² The surgical suite or operating room needs to be well lit, well ventilated, and include ample floor space for an electric operating table, emergency equipment, Mayo stand(s), instrument storage, electrosurgical equipment, and sink. It should convey a comfortable, yet

efficient, professional appearance and be easily and frequently cleaned. Ideally, it should convey an atmosphere that reflects a clean, meticulous, well-organized, high-quality medical facility.³ In the event of an emergency, the surgical suite should be able to accommodate emergency equipment and personnel. Table 4-1 shows a “shopping list” of items needed for a typical surgical suite.

Table 4-1. The Surgical Suite Shopping List

Necessary	Ideal
Surgical table	Pulse oximeter
Light source (overhead or portable LED)	Full crash cart with oxygen
Electrosurgery device	Smoke evacuator
Stool	Suction
Sharps and biohazard waste disposal	Full surgical scrub sink outside of OR
Mayo stand	
Waterless hand cleanser	

Design

While each dermatologist may have their own opinion regarding what is needed in their operating room, statutory requirements should be considered first before designing their suite. The American Academy of Dermatology has published guidelines of care for office-based surgical facilities that can be utilized as a starting point for surgical suite design.^{4,5} Table 4-2 shows sizing suggestions for rooms, doors, and ceilings in the surgical suite.

Table 4-2. Sizing Suggestions for Rooms, Doors, and Ceilings

Component	Sizes and Specifications
Procedure room	12' × 12' minimum ideally
Hallways	5' minimum
Doorways	32"–51"
Ceiling height	7' 10" minimum; 9' is ideal
Waiting room	Consider separate procedural/Mohs waiting room
Flooring	Smooth and monolithic is ideal

The surgical table should be located at the center of the room. There should be approximately 3 ft of clearance room at the ends of the table and, ideally, 4 ft at the sides to allow easy access to the patient by the dermatologic surgeon, surgical assistant, and circulating staff. A power outlet should ideally be wired into the center of the floor to eliminate power cords running across the floor to a wall socket.

Multiple electrical outlets in the surgical suite are essential, especially if a room is utilized for multiple procedures such as reconstruction, electrosurgery, and light-based procedures. When designing a surgical suite from the ground up, wiring all surgical rooms for 220 V would be wise in the event that lasers or other special equipment are added in the future.¹ Room access may be via a pocket door, rather than a swinging door, to permit the room to be separated from the rest of the office environment while maximizing floor space (Fig. 4-1).²

Figure 4-1. Representative surgical suite blueprint.

Temperature

The surgical suite should maintain a comfortable ambient temperature with relatively low humidity; generally, surgical rooms are kept at a cooler temperature than other offices, given the heat generated by lighting, surgical gowns, and other equipment. For the patients' comfort, extra blankets and pillows may be made available. Body warmers may be used for recovery, though these are generally not utilized in the outpatient setting. During long procedures, patients may benefit from a pillow behind their knees to reduce perceived back pressure.

Lighting

Proper lighting and visualization of the surgical field is of paramount importance when performing surgical procedures. Natural light in the surgical suite through sealed windows is encouraged. The room should have good general lighting with standard fluorescent or LED lights that illuminate the central working area. General room lighting may be augmented by a large, adjustable, ceiling-mounted overhead operating room light. Shadowless lighting delivering precision illumination is the ideal, and there are many options available.² Lights should be adjustable during surgery, which may be accomplished by using sterile disposable handle covers, sterilized aluminum foil, or autoclavable handles that can be screwed in place. Alternatively, eyeglass-mounted LED lights provide direct illumination for the surgical field and are increasingly becoming the norm as long-lasting battery packs coupled with a decreased price point make these the illumination technique of choice for many surgeons (Fig. 4-2).

Figure 4-2. Overhead-mounted operating room lights.

Sinks

The sink should be at a height that facilitates comfortable hand and arm washing. Some authors maintain that a surgical sink with foot pedals is preferable for the surgical suite.⁶ While more expensive than conventional sinks, they prevent contamination of the hands when turning off the faucet controls. They may be paired with foot-operated soap dispensers. Hands-free electronic sensors may also be used for sink activation. A sink depth of 18 to 24 in may be helpful to decrease splash and encourage a good water stream when hand washing (Fig. 4-3).⁷

Figure 4-3. Standard room stainless-steel sink.

Ergonomics

Though dermatologic surgeons rarely complain about physical stress or discomfort, they should be aware of some of the hazards of work-related injuries and how to avoid them. An appreciation of ergonomics, the study of fitting the job to the worker and altering the work environment and tasks to the capability of the one performing work, is very helpful when designing a surgical suite.^{8,9}

A 2007 survey of Mohs surgeons found that 94% of survey respondents experienced symptoms exacerbated by surgery including stiffness and pain of the neck, shoulders, and lower back, as well as headaches.¹⁰ Analysis of these surgeons found that ergonomic issues existed with operating room setup, awkward posture, poor positioning, length of procedures, and lighting. A similar survey of Mohs surgeons, conducted in 2010, found that 90% of respondents experienced musculoskeletal symptoms or injuries.¹¹ Again, the neck, shoulders, lower and upper back were the most commonly affected areas. These injuries were attributed to lack of ergonomic modifications

within the surgeons' practice, and were seen to start early in their career, at an average age of 35. Recommendations from these studies included modifying footwear, flooring, surgical instruments, operating position, lighting, and table height. Other surgical subspecialties, such as otorhinolaryngology and gynecology, report a similar incidence of musculoskeletal pain. A common theme among specialties is a lack of awareness and/or implementation of ergonomic principles.

Ergonomic professionals and resources, such as the OSHA website on Healthcare Wide Hazards (<https://www.osha.gov/SLTC/etools/hospital/hazards/ergo/ergo.html>) can be employed to optimize ergonomic interventions. Attention to these practices can improve day-to-day comfort and potentially career longevity.

Aesthetic considerations

Aesthetically pleasing healing environments can have a positive influence on patients, and many authors recommend the purposeful use of architecture, art, and music to improve the surgical experience for the patient.^{12–14} A 2013 study on patient anxiety while undergoing Mohs surgery found that the presence of music correlated with decreased anxiety and pain.¹⁵

A systemic review of the effectiveness of art, music, or appealing interior design was performed, and 48 studies were examined.¹⁶ The meta-analysis concluded that these low-cost interventions help alleviate postoperative pain, anxiety, and even resulted in decreased blood pressure and heart rate compared to control groups. Simple adjustments to the surgical suite, such as introducing a calming environment with music or pleasing interior design can be beneficial in reducing patient qualms over surgical procedures. Self-selection of the music by the surgical patient is an effective and low-cost intervention to minimize anxiety and enhance well-being. Newer technologies permit easy access to music whether using a CD player, radio, as well as free or low-cost computer-based applications such as Pandora or Spotify. Moreover, interior design features such as outdoor photographs, spacious rooms, and architectural window features providing more sunlight were found to have positive effects on perceived anxiety and postoperative pain (Figs. 4-4 and 4-5).

Figure 4-4. In-room artwork may induce a calming environment.

Figure 4-5. Spacious architecture and natural sunlight from sealed windows may improve the surgical experience.

EQUIPMENT

Emergency equipment

Surgery limited to the skin and subcutaneous tissue, when performed under local anesthesia, does not require the need for emergency equipment and continues to be exempted by most state regulations. It remains the responsibility of the physician to ensure that the surgical facility is in compliance with local and state government regulatory bodies.

More advanced surgical suites should be equipped with an emergency crash cart in case of cardiopulmonary arrest or life-threatening drug reaction. Key office staff should be trained in basic CPR and ACLS. In addition, an emergency plan for patient transfer to a hospital should be in place.

As a general guideline, an emergency crash cart should include the following: automated external defibrillator (AED), oropharyngeal airway, laryngoscope with endotracheal tubes of various sizes, positive-pressure ventilation device with airways of various types and sizes, oxygen tank with

delivery system, IV catheters of various sizes, bags of intravenous fluids, prefilled syringes/ampules including epinephrine, atropine, dextrose, lidocaine, sodium bicarbonate, hydrocortisone, naloxone, flumazenil, diphenhydramine, and furosemide (Table 4-3).

Table 4-3. Crash Cart Contents (Based on AHA Guidelines)

Equipment	Drugs
Airway (oral and nasal) all sizes	Aspirin 81-mg tablets
McGill forceps, large and small	Nitroglycerin Spray or 0.4-mg tablets
King Airway Set (3) Eliminates the need for Laryngoscope and Endotracheal tubes	Dextrose 50% (Dextrose 25% if treating pediatrics)
Bag Valve Mask (Adult and Pediatric)	Narcan 1 mg/mL (6)
Nasal Cannula	Epinephrine 1:10,000 Abboject (3)
Non Rebreather Oxygen Face Masks (3 sizes)	Atropine Sulfate 1 mg Abboject (3)
IV Start Packs	Amiodarone 150 mg vial (4)
Normal Saline Solution (1000-mL bags)	Epi Pen (2)
IV Tubing	Epi Pen Jr (2)
Angiocaths (various sizes)	Solumedrol 125 mg vial
10-mL Normal Saline Flush Syringes (3)	Benadryl 50 mg vial (2)
Gauze	Adenosine 6 mg (4)
Alcohol Preps	Lopressor 10 mg (2)
Monitor with Defibrillator or AED	Cardizem 20 mg vial (2)
Syringe nasal adaptor (nasal narcan atomizer)	Pronestyl (Procainamide) 1 g in 10 mL 100 mg/mL vial (1)

Other emergency items recommended for the surgical suite include blood pressure/pulse monitoring, a pulse oximeter, a suction device, fire extinguisher, and eyewash station.

The surgical table

The surgical table is the centerpiece of the operating room and one of the dermatologic surgeon's most important equipment purchasing decisions. The surgical table should be electrically foot operated, easily adjustable, well padded, and comfortable. Variables to consider include table width and entry height. While a wider table may be more comfortable for larger patients, a narrow table allows the dermatologic surgeon to access the surgical site more easily and maintain good ergonomic posture. Surgical tables with a low entry height are very important for the elderly or disabled, and facilitate easy transfer from wheelchairs. Other accessories to consider include armrests, headrests, armboards, footboards, and stirrups. Patients feel less anxious and more secure if they can easily rest their arms and shoulders without fear of rolling off the table.

Adjustability is another consideration when choosing a surgical table. The importance of maintaining flexibility in patient positioning cannot be exaggerated. The tilt adjustment should allow the table to place the patient in the Trendelenburg position, helpful when managing vasovagal reactions. A useful tip for automated tables is to utilize the Trendelenburg position as a preset, so that it can be accessed rapidly.

With the increasing prevalence of obesity worldwide, newer facilities often consider measures for obese patients when choosing their surgical table and designing their surgical facility. However, despite the newest equipment, access to the surgical site in these patients remains challenging.

Surgical stools

The dermatologic surgeon should be able to stand or sit when necessary. A comfortable, sturdy, foot adjustable, rolling surgical chair should be located on each side of the surgical table. There are a variety of surgical stool designs available, including those with back support and arm rests.

Electrosurgery and hemostasis

An electrosurgical device for hemostasis is essential in dermatologic surgery.¹⁷ In electrosurgery, high-frequency, alternating electric current is passed through the skin to generate heat. It requires a power supply and a handpiece for the electrode. A sterile dedicated electrode tip should be used for each patient. Electrosurgery includes electrofulguration, electrodesiccation, electrocoagulation, electrosection, and thermocautery. Electrosurgery may be monoterminal, monopolar, or bipolar. A wide variety of devices are available for electrosurgical hemostasis. For a full discussion of electrosurgery and hemostasis, see [Chapter 16](#).

The use of a smoke evacuator should be considered for several reasons. The smell of burning skin can be disconcerting to patients, and the plume may lead to respiratory irritation in patients and staff. In addition, while there is no documented transmission of infectious diseases through surgical smoke, there is a theoretical potential for viral particle transmission.^{18,19}

Mayo stands

Mayo stands are an essential part of the surgical suite, allowing moveable easy access to surgical instruments during procedures. Some surgeons prefer two Mayo stands to place surgical instruments on one and wound dressing materials on the other.² The options to consider when selecting a Mayo stand include size, movement, mechanism for lifting and lowering the platform, the base of the stand and possible presence of a circular base for kick-bucket placement, and the rolling mechanism.

Safety and waste containers

Dermatologic surgery exposes surgeons and assistants to potentially dangerous blood-borne pathogens. All surgical suites or operating facilities should be equipped with personal protective equipment such as masks, eye protection, and gloves.

State and federal laws govern medical waste disposal. It is important to review relevant information from regulatory agencies to ensure that the surgical suite meets local, state, and federal standards. The surgical suite needs to be equipped with proper waste disposal devices for all sharps and biohazardous materials. Kick buckets, stainless steel waste receptacles on wheels, are easily moved for ready access and disposal of waste and should be emptied between each procedure.^{1,2}

There are three recommended types of waste disposal (Table 4-4).

Table 4-4. Waste Disposal Options

Waste Type	Disposal Method	Relative Cost
Sharps	Container should be durable, closable, and puncture and leak resistant	\$\$
Contaminated waste; soaked with blood	Placed in a biohazard container or red bag	\$\$\$
Non-blood-soaked waste	Dispose of in standard fashion as with normal waste	\$

1. Sharps disposal container should be durable, closable, and puncture and leak resistant.
2. Contaminated waste should be placed in a biohazard container or “red bag.” The method of disposal may require expensive services for elimination of this by-product.

3. Noncontaminated waste, that is, paper drapes, paper towels should be disposed of like normal waste.

CONCLUSIONS

When designing and building a dermatologic surgery suite, it is important to consider future growth. Erring on the side of larger operating rooms with abundant storage permits future expansion and flexibility. Consultation with colleagues, architects, contractors, interior designers, and occupational health specialists is recommended. Most importantly, designing and building the surgical suite takes a significant amount of time, effort, and planning, and should represent a source of both pride for the surgeon and comfort and safety for the patient.

CHAPTER 5 Surgical Instrument Selection

Michael S. Lehrer
Ashish C. Bhatia
Aashish Taneja

SUMMARY

- Surgical instrument choice may have a direct impact on outcomes, and certainly leads to less traumatic and faster procedures.
- Investing in high-quality instruments is generally a wise decision.
- The highest-quality instruments are the longest lasting, provide the best surgical outcomes, and allow for optimal comfort and speed. Using inadequate instrumentation may lead to need for frequent replacement, poor performance, and tissue damage.
- While the majority of procedures may be completed with a few basic instruments, there is a wide array of available instruments that may be used for specialty procedures.

Beginner Pearls

- Consider purchasing instruments at conferences in order to both sample the range of choices and save on costs.
- Surgical packs do not require an exhaustive array of instruments.
- When training staff, including a laminated photograph of the surgical pack above the area where instruments are washed and packaged is a helpful training tool.

Expert Pearls

- Consider color-coding instrument packs for ease of organization and consistency.
- Maintain basic surgical packs and add specialized instrumentation as needed. Instruments used in less than 25% of cases may be kept in separate packs as long as they are easily accessible.
- When using larger suture needles, such as those on 2-0 suture, be sure to use larger and heavier needle drivers, as fine needle drivers may be loosened by clamping on more robust needles.
- Supercut scissors are denoted by black handles. The upper blades of these scissors are honed with a double, rather than single, bevel, similar to the blade of a high-quality knife or scalpel and the lower jaw is serrated. These scissors optimize tissue cutting in most circumstances, but the sharp blade is easily dulled.
- Some surgeons use a skin hook in place of forceps for skin reflection during suturing to minimize the risk of tissue strangulation.

Don't Forget!

- Beware the temptation to create overly comprehensive surgical packs. Many accomplished dermatologic surgeons work with a basic set of high-quality instruments.
- Suture-tying platforms are extremely helpful; it is always preferable to use toothed forceps with platforms rather than nontoothed forceps, as the latter increase the risk of tissue strangulation.

Pitfalls and Cautions

- Always autoclave instruments in the open position to avoid buckling.
- Avoid using supercut scissors to cut anything but tissue.
- Staff should always be responsible for their own sharps disposal, which should be performed before the used instruments are removed from the room.
- The jaws of a needle driver may be smooth or have fine teeth or ridges. Small teeth may assist in gripping the needle, but may also damage the suture material during handling and tying.
- The most common risk to both surgeon and assistant in dermatologic surgery is needle puncture, though the risk of disease transmission is low when using closed-bore sewing needles.

CHAPTER 5 Surgical Instrument Selection

INTRODUCTION

Optimal outcomes in dermatologic surgery require selection of the most appropriate surgical instruments. While the majority of procedures may be completed with a few basic instruments, there is a wide array of available instrument quality and selection.

Modern instruments are made from various metals or alloys, including stainless steel, chromium nickel, and tungsten carbide. Though numerous manufacturers are available, most readily available precision instruments are manufactured by several companies in Germany. In general, the highest-quality instruments are the longest lasting, provide the best surgical outcomes, and allow for optimal comfort and speed. Using inadequate instrumentation may lead to the need for frequent replacement, poor performance, and tissue damage.

In general, instruments used in dermatologic surgery are small, fine, and lightweight, allowing for proper atraumatic handling of delicate tissue and minimal operator fatigue. However, the thickness and quality of skin encountered in dermatology vary greatly, and specific instruments are designed for each of these skin types. A detailed description of instrument types and patterns, and their eponymous names, could fill a surgical equipment catalog. This chapter is intended as a guide to the general categories of instruments available, with emphasis on those instruments most commonly encountered.

Biopsy instruments

Small samples of skin are frequently needed prior to performing comprehensive dermatologic surgery procedures. While standard dermatologic surgery instruments such as scalpels may be used, specialty instruments have been developed to simplify biopsy procedures.

Punch biopsy instruments, or punches, are designed with a cylindrical cutting blade attached to a handle (Figs. 5-1 and 5-2). Though reusable devices were originally used, most have been replaced by disposables. These disposable punches provide both sterility and a razor sharp edge. Useful punches range from 2 to 8 mm in diameter. An elliptically shaped punch has also been developed to facilitate elegant closure. However, many surgeons find this device to be difficult to use, as the punch cannot be rotated to enhance cutting.

Figure 5-1. Punch biopsy instruments are available in an array of sizes and configurations.

Figure 5-2. Some punch devices are autoclavable.

A shave biopsy may be performed with any sharp-edged cutting instrument. A double-edged razor blade, snapped in half, provides an extremely sharp and inexpensive tool for shave biopsy. By altering the curvature of the blade between their fingers, the surgeon may adjust the depth of the biopsy. Scalpel blades are also readily available, and may be stabilized by wrapping the base of the blade in its foil packaging. The Dermablade is a commercially available blade with plastic support handles. This may provide improved grip and safety to the surgeon as compared to working with a snapped double-edged blade, though it is significantly more expensive and most veteran dermatologic surgeons are expert at handling snapped double blades.

Curettes

The curette is a surgical instrument designed for scraping ([Figs. 5-3](#) and [5-4](#)). The handle may be of various weights, lengths, and textures. The head, usually crafted from the same piece of metal as the handle, may be round or oval, cup or ring shaped, ranging from 1 to 10 mm wide, and is sharp on one side. Curettes are most commonly used to remove or destroy benign or malignant lesions. They may also be used to debulk and delineate tumor

margins prior to excision or Mohs surgery. As with other surgical instruments, the most appropriately sized instrument for the procedure should be selected to facilitate destruction while avoiding surrounding tissue damage.

Figure 5-3. Curettes are available in various weights, lengths, and textures.

Figure 5-4. Larger curettes may be used for thicker tumors.

Curettes are available in both disposable and reusable designs. Disposable curettes have a sharper tip, and function similarly to a curved scalpel blade. Most surgeons favor the reusable instruments, as their blunter edge provides improved sensory feedback, allowing the surgeon to better differentiate between various tissue types.

Scalpels

Scalpels may be used for cutting, puncturing, dissecting, manipulating specimens, and scraping. They generally consist of a handle and a blade. Both the handle and blade are available in numerous sizes and materials. Selection is based upon both surgeon preference and the surgical application.

Scalpel blades are disposable, individually wrapped, and pre-sterilized. They may be made of carbon steel or stainless steel. Carbon steel blades are sharper, though they dull more rapidly. Stainless steel blades are not as sharp but last longer. Blades may be coated in silicon or polytetrafluoroethylene to minimize tissue drag and increase longevity. These may be particularly useful in longer procedures or multi-staged Mohs surgical procedures.

The most common surgical blades in dermatologic surgery are the 15, 15c, 10, and 11 blades. These blades are designed to fit a variety of available handles. The 15 blade's small size and gentle curvature make it optimal for the majority of skin procedures. The sharp tip is used to initiate cuts, while the broader belly provides a longer surface for enhanced contact. With the handle held at 30 degrees to the skin, longer smooth cuts may be made. The 15c blade is a smaller variant, used to treat very delicate skin; its sharper carbon blade also dulls faster. The 10 blade also shares a similar shape but is significantly larger, making it optimal for thicker skinned areas such as the back. The 11 blade is triangular with a straight edge that tapers to a sharp point. It is usually used in a stabbing motion for incision and drainage.

Each of the above blades may be fitted interchangeably on a variety of handles (Fig. 5-5). The flat number 3 handle is most frequently encountered. It is well suited to the majority of procedures and is available with an imprinted metric ruler. The cylindrical Siegel handle has a gnarled grip and is useful for smooth, curved motions, such as removing round, beveled Mohs surgery specimens.

Figure 5-5. Surgical blades may be fitted interchangeably on a variety of handles.

An alternative handle and blade combination is the miniblade or Beaver system. In this system, smaller blades are inserted into a collet, which is tightened with rotation. Blades are available in a variety of shapes and curvatures. This system may be used in smaller, narrow spaces such as the ear canal or medial canthus.

Scissors

Surgical scissors come in a great variety of shapes and sizes, each designed for a specific task. Though the choices are dizzyingly extensive, the selection of a few optimal pairs of scissors may enhance comfort and surgical outcomes.

The basic anatomy of scissors consists of three parts: the handle, the blade, and the tip. The handle may be long or short. Short-handle scissors are most commonly used by dermatologic surgeons, as they provide enhanced control when working with delicate tissue. Longer handles provide increased leverage and cutting strength and may be necessary when working in cavities, such as when creating a flap for a facelift, or during extensive undermining. Handles are most often straight, though curved or bent handles are available. These alternative shapes may improve visibility or approach for difficult-to-reach areas.

Scissor blades are available in varying shapes and quality. In the most basic design, the blade is formed from the same piece of stainless steel as the handle. Such scissors are inexpensive and well suited for basic procedures, for cutting sutures, and for forming bandages.

The lower blade of a scissor may be serrated to increase stability and reduce slippage. These fine teeth are difficult to visualize, but may be easily felt by running the finger gently along the blade. The serrated blade is particularly useful when working with thin skin and for trimming the edges of delicate flaps and grafts. Scissors may be purchased serrated, or this feature may be added after manufacture.

Higher-quality scissors may be enhanced with tungsten carbide inserts. This material reinforces the blade, improving cutting and providing a longer life without dulling. Tungsten carbide is brittle, and may be damaged if instruments are dropped or mishandled, though the insert may be replaced.

when dulled or damaged. Surgical instruments with tungsten carbide inserts are identified by their gold handles.

Supercut scissors are denoted by black handles. The upper blades of these scissors are honed with a double, rather than single, bevel, similar to the blade of a high-quality knife or scalpel. The lower jaw is serrated. These scissors optimize cutting in most circumstances. The sharp blade, however, is easily dulled. Supercut scissor should be reserved for tissue and should never be used to cut suture.

Scissor tips may be pointed, blunt, or hooked. Pointed tips are useful for precise trimming and shaping and for aggressive dissection in areas of difficult scissor insertion. Blunt tips are safer for undermining around delicate structures and for freeing flaps and grafts. The single-hooked tip may be used to assist with suture removal.

By altering handle, blade, and tip shapes and sizes, many hundreds of scissor designs have been introduced. While a detailed description of each is beyond the scope of this chapter, several common types comprise the majority of our armamentarium.

Iris scissors are the most commonly used scissor in dermatologic surgery (Fig. 5-6). Originally developed for the eyelid, these have wide application for facial and other cutaneous surgery. These usually measure approximately 4 inches, may have straight or curved blades, and may have sharp or blunt tips. Their relatively long handle-to-blade ratio provides excellent accuracy while retaining mechanical advantage. The blepharoplasty scissor is a specialized iris scissor with a gentle curve, blunt tips, tungsten carbide inserts, one serrated blade, and one flattened blade. In addition to its original intention, this scissor may be particularly useful for dissecting cysts, and for debeveling and undermining wounds prior to closure.

Figure 5-6. Numerous scissors are available for use in dermatologic surgery.

Gradle and tenotomy scissors have a high handle-to-blade ratio and a small, delicate, sharp tip that is tapered to a fine point with a gentle curve (Fig. 5-7). Their fine features and precision make them ideal for working with delicate tissues or for harvesting thin stages during Mohs surgery.

Figure 5-7. Gradle scissors have a high handle-to-blade ratio and a small, delicate, sharp tip that is tapered to a fine point with a gentle curve.

Operating scissors are larger, heavier instruments more commonly used in general surgery. While these have limited use in dermatologic surgery, some may be helpful in larger cases. Mayo scissors are heavy, with a nearly one-to-one handle-to-blade ratio. These may be used for coarse dissection.

Metzenbaum scissors are heavier, with a high handle-to-blade ratio for increased leverage and reach.

At the more delicate end of the spectrum are Westcott and Castroviejo scissors (Fig. 5-8). These spring-loaded instruments are held like a pencil and squeezed closed to cut. The blade reopens when released. They generally have fine, pointed tips, and are particularly useful when working with thin periorbital skin.

Figure 5-8. Castroviejo scissors are spring-loaded and held like a pencil.

The scissors discussed above are intended for tissue and may be damaged when working with other materials. A surgical tray should also contain scissors for cutting suture. Suture-cutting scissors may include a basic stainless steel iris scissor or a standard operating scissor, which comprised of heavier blades with one blunt and one sharp tip. Bandage-cutting scissors tend to be large and have blunt tips to protect the patient's skin during the removal of the bandage (Fig. 5-9). One blade is generally flattened to slide under the dressing without damaging the underlying integument. For suture removal, the Northbent scissor is curved with a hooked blade, the Spencer scissor is straight with a hooked blade, while the O'Brien scissor has a short-angled blade that allows the fine tip to be introduced below suture loops (Fig. 5-10).

Figure 5-9. Bandage-cutting scissors tend to be large and have blunt tips to protect the patient's skin during removal of the bandage.

Figure 5-10. For suture removal, the Northbent scissor is curved with a hooked blade.

Forceps

Forceps are used to hold or grasp items such as tissue, sutures, or other materials within the surgical field. They are generally held between the thumb and index finger like a pencil. They are pressed to close, and are designed to reopen with released. As with other surgical instruments, forceps are available in a variety of sizes and weights. While a matter of personal preference, the most delicate instrument useable for the procedure should usually be selected to avoid tissue damage.

Forceps handles are usually stainless steel. They are available in a variety of weight and lengths. Grips may be ridged or gnarled for improved grip when wet. Handles may also be drilled or fenestrated for weight reduction.

Surgical forceps are available with or without teeth. Those without teeth are referred to as dressing or bandage forceps, and are for the most part, not intended to handle the skin. Tissue forceps, on the other hand, have delicate teeth at the tips. When used gently, these tips allow the skin to be manipulated without crushing or leaving marks on the skin. Teeth are available in various weights and sizes to correctly suit the tissue. The most commonly used tooth pattern is 1×2 , meaning one tooth on one tip that fits between two teeth on the other tip. However, multiple tooth patterns such as 2×3 through 8×9 are available.

Some forceps are available with a suturing or tying platform ([Fig. 5-11](#)). This is a slightly raised, flattened area placed directly behind the teeth. This platform allows the needle to be gripped securely without twisting or turning. The needle can, therefore, be passed directly from the needle driver to the forceps without touching the needle with the fingers. This may greatly reduce the risk of needle stick to the surgeon. For optimal grip and ease of maintenance, this platform may be constructed of gnarled tungsten carbide. Such forceps are denoted, like all tungsten carbide instruments, with gold handles.

Figure 5-11. Some forceps are available with a suturing or tying platform.

The most common forceps design used in dermatology is the Adson (Fig. 5-12). These have a broad handle that tapers to a narrow tip. This tip may be serrated, smooth, or toothed; Adson forceps are available with or without tying platforms. Long, heavy handles or lightweight, fenestrated handles are available. By varying these characteristics, Adson forceps suited for nearly all dermatologic surgery procedures have been produced. A common variation is the Brown–Adson forceps, in which a platform of minute teeth is placed at the tip.

Figure 5-12. The most common forceps design used in dermatology is the Adson.

For more delicate procedures, small forceps with a longer tip-to-handle ratio are available. Iris forceps are simple, inexpensive, and slowly taper from handle to tip. Bishop–Harmon forceps are short, with fenestrated handles and well-defined, long, delicate tips. These are available with or without teeth. Jeweler’s forceps are similarly delicate, with tapered sharply pointed tips.

Nontissue handling forceps are also commonly used in dermatologic surgery. Those with smooth tips may be useful for gripping sutures or foreign bodies. The Swiss cilia forceps is short, with a smooth, angled, pointed tip (Fig. 5-13). This is particularly useful in suture removal. Forceps with serrated tips increase the gripping strength and may be used to manipulate gauze within a surgical field. While they may also be used to grasp cysts or lipomas, their use on vital tissue may lead to tissue damage or necrosis.

Figure 5-13. The Swiss cilia forceps is short, with a smooth, angled, pointed tip.

Needle drivers

Needle drivers, or holders, are clamped instruments intended to hold a surgical needle securely when suturing. When closed, a ratchet activates to grip the needle without effort. To release the clamp, the handles are separated laterally. Designed similarly to scissors, these are available in varied weights, handle lengths, tip shapes, and tip materials. While designs vary, the smallest instrument that can be comfortably used to execute the task is recommended. Further, smaller needle drivers are optimized to hold smaller needles, and may be damaged by larger needles, while larger drivers are intended to hold larger needles, and may bend smaller ones.

The jaws of a needle driver may be smooth or have fine teeth or ridges. Small teeth may assist in gripping the needle, but may also damage the suture material during handling and tying. Horizontal ridges may be found in other needle driver jaws. These are intended to keep the surgical needle from twisting. However, fine sutures may pass through these ridges when gripping the suture to perform an instrument tie. Rough-surfaced tungsten carbide inserts are available to improve instrument durability and increase needle

grip. These are also replaceable. As usual, these instruments are denoted by gold handles, and are more expensive than other options.

The eponymous Webster, Halsey, Baumgartner, Crile–Wood, and Mayo drivers are most commonly used in dermatologic surgery (Fig. 5-14). These are similarly shaped, with long handles and short tips. They are available in various weights and lengths to optimize needle handling and physician comfort. Most are available with each of the above-discussed tip types.

Figure 5-14. A variety of needle drivers are available for dermatologic surgery.

For more delicate procedures, particularly on eyelids, Castroviejo needle holders may be used. Similar to the Castroviejo scissor, these are delicate spring-loaded instruments. Unlike most needle drivers, these are available in both locking and nonlocking variants.

The Olsen–Hegar needle holder contains a scissor just proximal to the needle holding jaws (**Fig. 5-15**). These are often favored by a surgeon working without assistance. It may be used to suture and cut suture without changing instruments. However, care must be taken to avoid cutting the suture material accidentally while working.

Figure 5-15. The Olsen–Hegar needle holder contains a scissor just proximal to the needle holding jaws.

Hemostats

Hemostats are grasping devices, similar to forceps, but with a ratcheted locking mechanism like a needle driver (**Fig. 5-16**). These are used to temporarily clamp bleeding vessels during surgery; vessels can later be

sealed with electrosurgery or ligated with sutures before the hemostat is removed. Like needle drivers and forceps, hemostats may vary in length, tip size, curvature, and degree of serration. Common variants include the Jacobsen, Halsted, and Hartman. Small, lightweight hemostats, colloquially referred to as “mosquitos,” are most often used in dermatologic surgery.

Figure 5-16. Hemostats are grasping devices, similar to forceps, but with a ratcheted locking mechanism like a needle driver.

Skin hooks

The skin hooks used in dermatologic surgery are long, tapered instruments with a small, sharp hook at the end ([Fig. 5-17](#)). These are used to delicately manipulate tissue to improve field visualization, assess flap movement, or reflect skin edges during undermining or electrosurgery. Some surgeons use a skin hook in place of forceps for skin reflection during suturing. The chief disadvantage of the skin hook is the sharp tip and resultant risk of puncture injury to the surgeon or assistant.

Figure 5-17. Skin hooks used in dermatologic surgery are long, tapered instruments with a small, sharp hook at the end.

Skin hooks are available in single-, double-, or multi-pronged patterns, with the latter being described as rakes. Larger, wider instruments may be useful when manipulating heavy truncal skin, while delicate single-tipped hooks are most useful on the face.

Miscellaneous instruments

The chalazion clamp consists of a flat arm opposed by a ring. As these are clamped down on a mobile, vascular surface such as the lip, eyelid, or earlobe, the ringed arm provides stabilization and hemostasis, while the flat arm provides a backing surface against which the tissue can be cut. The clamp tension is adjusted by a thumbscrew, which can be gradually tightened or released. It is important to release the clamp as soon as possible to avoid tourniquet necrosis. Chalazion clamps are available in a variety of shapes and sizes. Rubber-coated clamps are recommended if electrosurgical instruments are to be used. Double-action nail cutters are also useful in nail

procedures, and can be used in place of rongeurs when working with superficial bone (Fig. 5-18).

Figure 5-18. Double-action nail cutters are also useful in nail procedures, and can be used in place of rongeurs when working with superficial bone.

Periosteal elevators are elongated flat instruments designed to lift the periosteum from the bone (Fig. 5-19). In dermatologic surgery, they are also frequently used to lift the nail plate off the nail bed. Bone chisels have a sharpened, flattened head and a broad handle. These may be struck with a small hammer to biopsy bone, usually if invasive neoplasm is suspected during Mohs surgery.

Figure 5-19. Periosteal elevators are elongated flat instruments designed to lift the periosteum from the bone.

Towel clamps allow sterile drapes to be firmly anchored in place (Fig. 5-20). They may also be used to keep electrosurgery handles within the operating field. Some surgeons additionally use the towel clip to hold large wounds together prior to suturing, or to grip a cyst or lipoma during extirpation.

Figure 5-20. Towel clamps allow sterile drapes to be firmly anchored in place.

Corneal shields are available in multiple sizes and may be placed over the eye to protect the cornea during periorbital procedures (Fig. 5-21). These are available both in plastic, which is both inexpensive and optimal for use during electrosurgery, and in stainless steel. Corneal shield placement requires anesthetic eye drops, careful sizing, and correct technique to avoid corneal irritation or abrasion.

Figure 5-21. Corneal shields are available in multiple sizes and may be placed over the eye to protect the cornea during periorbital procedures.

Sharps safety

The most common risk to both surgeon and assistant in dermatologic surgery is needle puncture. Thankfully, the risk of disease transmission is low when using closed-bore sewing needles. Undoubtedly, the most critical protective measure is mandatory glove use when dealing with sharps of any kind.

Loose suture needles on the surgical tray are a common source of needle injury to both the surgeon and assistant. Several systems have been developed to minimize risk. Most commonly, all sharps are kept maintained in one area of the tray. In larger cases, however, multiple needles may be used. These may be kept organized with dedicated suture needle boxes, with a disposable foam block or pincushion placed on the field, or by placing a magnet under the surgical tray to attract and organize sharps.

To avoid scalpel injury at the conclusion of a procedure, a surgical blade remover is required to separate disposable scalpel blades from the handle. The most common devices require two hands: one to hold the scalpel, and the other to operate the clamp and remove the blade (Fig. 5-22). With

practice, these are safe, reliable, and cost effective. Counter- or wall-mounted devices have also been created to allow for one-handed operation. With these devices, the scalpel is inserted, blade first, into the machine and the blade is safely removed. While efficient, these require frequent replacement.

Figure 5-22. To avoid scalpel injury at the conclusion of a procedure, a surgical blade remover may be used to separate disposable scalpel blades from the handle.

Instrument maintenance and sterilization

Careful instrument maintenance and sterilization are critical to ensure functional equipment and provide patient safety. After surgery, the instruments should be cleaned. First, all debris must be removed from the instruments. Organic debris may allow for the growth of micro-organisms, and may interfere with sterilization. This is most commonly performed by soaking followed by hand scrubbing. Ultrasonic cleaning may also be used. Next, the instruments should be dried and treated with lubricant such as instrument milk. The instruments are then packed in a self-sealing pouch, metal box, or plastic tray. They should be loosely packed, with needle

drivers and scissors in the open position. Surfaces in close contact may not be fully treated during the sterilization process. The pack should then be sterilized by steam autoclave. Though other systems, such as gas, dry heat, and chemical sterilization, are theoretically possible, these are generally less reliable and not frequently used by the dermatologic surgeon. The autoclave should be routinely tested to ensure adequate sterilization.

With appropriate maintenance, many surgical instruments may last for the career of the surgeon. Scissors may be sharpened by the manufacturer or by companies that will provide on-site service. Tungsten carbide inserts in needle drivers, scissors, and forceps may be replaced. Stiff instruments can be lubricated or cleared of mineral deposits with a solution of vinegar and water.

A basic instrument setup for dermatologic surgery procedures

- Blade handle
- Needle driver
- Suture scissors
- Tissue scissors (Supercut iris scissors used frequently)
- Forceps (Adson's with teeth and platforms used frequently)
- Hooks (optional)
- Hemostat (optional)

Instrument packs for surgery

Instruments may be packed and sterilized individually, so that the appropriate instruments may be selected for each surgical case. However, most surgeons find it more convenient to pack multiple instruments together. The most basic surgical kit can be prepared with a scalpel handle, needle driver, scissor, and forceps. Other instruments can be added as needed.

Dermatologic surgeons vary in their approach to surgical pack preparation. At one end of the spectrum, a surgeon may favor a single pack style for all surgical cases, while other surgeons utilize two types of packs (face and body) and still others use three types of packs (face, body, and

extremity). Typical surgical kits contain a scalpel handle, needle driver, tissue forceps with tying platform, a tissue-cutting scissor (either blepharoplasty, supercut iris, or both), a skin hook, a hemostat, a suture-cutting scissor, and surgical gauze. Additional specialty instruments are individually packed and available in the operating room.

CONCLUSIONS

The selection of proper surgical instruments is critical to providing high-quality, safe, and effective care in dermatologic surgery. This chapter is intended only as a guide to the overwhelming number of instrument choices available. Individual selections may be based upon the scope of procedures to be performed, the expertise and preferences of the individual surgeon, and financial limitations. Purchasing the highest-quality instruments, and correctly maintaining them, should provide long-lasting and efficient instruments.

Finally, in choosing instruments, there is no substitute for practical experience. No two surgeon's hands or skills are identical. Instrument shapes, sizes, and balances likewise vary widely. The surgeon should handle and examine a range of choices at surgical conferences or with dealer's representatives. Individual instruments can be purchased and tried before an office is fully equipped. Through experimentation and experience, comfortable and efficient instruments should be found.

CHAPTER 6 Suture Materials and Needles

Jonathan Kantor

SUMMARY

- Over the past several decades, suture materials have improved dramatically.
- The needle may be as or more important than the suture material itself in promoting an ideal surgical outcome.

- Keep in mind that the greatest differentiator between suture brands is needle quality rather than the suture material itself.
- Knot tying should be performed with an eye to creating a secure knot without adding undue bulk to buried sutures.

Beginner Pearls

- Most needles used for skin and soft tissue reconstruction are 3/8 circle in diameter and reverse cutting.

Expert Pearls

- A semicircular P-2 needle may be used for narrow closures, such as those sometimes encountered on the nose, and a cutting needle, with the sharp edge on the inside of the curve, may be useful for nasal reconstruction where the thin atrophic dermis may be cut by the superficially running outside edge of a reverse cutting needle.
- Since cutting and reverse cutting needles have a triangular tip, the orientation of the cutting end is indicated by whether the triangle on the box is pointing up (cutting) or down (reverse cutting).

- In order to minimize the risk of needle-stick injury, it is possible to grasp the suture material approximately 6 to 10 cm from the needle swage between the thumb and index finger of the left hand, allowing the needle to drop down below the hand. Since the needle is hanging freely and is not under tension, there is little chance for a needle-stick injury.
- Attention to technique, coupled with choice of a sufficiently large needle for the closure in question, may go a long way to optimizing surgical outcomes.

Don't Forget!

- Any suture, including absorbable sutures, may be used for transepidermal suture placement, which may permit the use of a single suture pack for both buried and epidermal sutures.

Pitfalls and Cautions

- A single click of the needle driver locking mechanism is sufficient for locking the needle, and cranking down on the needle driver excessively will result in a loosening of the locking mechanism, leading to inadvertent suture needle slippage in the future.

- The most frequent error encountered by novice dermatologic surgeons is using a needle that is too small for a given anatomic location, or using a technique that does not permit the needle to pass naturally and smoothly through tissue.
- When tying a deep suture, it is generally desirable to pull the suture strands together as tightly as possible, secured with a stable knot. For transepidermal sutures, since the goal of suture placement is wound-edge apposition, placing the minimal necessary tension across of the surface of the wound is a must; over-tightening these sutures will lead directly to strangulation, necrosis, and—at a minimum—track mark formation.

CHAPTER 6 Suture Materials and Needles

INTRODUCTION

Over the past several decades, suture materials have improved dramatically. Three thousand years ago, suture materials were composed of easily processed plant or animal materials affixed to bone or metal. In the middle ages, suture material made from sheep's intestine was introduced, and sterile catgut suture was first used in 1906. In the mid to late 20th century, advances in chemistry and manufacturing led to the production of the first synthetic sutures, and the availability of swaged needles over the past few decades has improved safety for both patient and surgeon while improving operative efficiency.

NEEDLES

A wide variety of suture materials are available, all with variable handling characteristics, tissue reactivity, absorption characteristics, and costs. While much attention is paid to suture material, the needle may be as or more important than the suture material itself in promoting an ideal surgical outcome. Needles vary by manufacturer and even by suture material, and utilizing the most appropriate needle for the task is critical. Even the most accomplished surgeon will perform in a less-than-ideal fashion if their instruments or needle choices are flawed.

Most needles used for skin and soft tissue reconstruction are 3/8 circle in diameter, and most needles used for skin and soft tissue reconstructions are reverse cutting in nature (Fig. 6-1). There are, however, important exceptions

to this rule. For example, a semicircular P-2 needle may be used for narrow closures, such as those sometimes encountered on the nose, and a cutting needle, with the sharp edge on the inside of the curve, may be useful for nasal reconstruction where the thin atrophic dermis may be cut by the superficially running outside edge of a reverse cutting needle.

Figure 6-1. The suture needle.

The two largest manufacturers of suture material used in cutaneous surgery are Ethicon and Covidien, though many other companies produce high-quality products as well. While the suture size is governed by USP guidelines (the larger the number of zeros, the smaller the suture), needle size and configuration is largely proprietary. Thus, the surgeon must be comfortable understanding the various needle sizes and configurations of the various manufacturers. Suture material packaging does include a cross-sectional image of the needle, permitting some comparison between companies. Of note, Covidien does not (except on its website) refer to any of its needles as reverse cutting; instead, they label cutting needles as conventional cutting and reverse cutting needles as cutting. These distinctions are important when choosing suture, and many suture type and needle combinations are only available with a finite number of permutations. Since cutting and reverse cutting needles have a triangular tip, the orientation of the

cutting end is indicated by whether the triangle on the box is pointing up (cutting) or down (reverse cutting).

The material used to make the needles themselves also varies considerably between manufacturers, as proprietary alloys are used to maximize the strength and durability. While Ethicon and Covidien products are used most often in skin and soft tissue reconstruction, many other reputable companies manufacture suture material, and individual preferences may vary widely.

Suture materials

While the needle has a major effect on the ease and efficiency of the surgical procedure, suture material choice also has the potential to impact wound closure significantly. Any suture, including absorbable sutures, may be used for transepidermal suture placement, which may permit the use of a single suture pack for both buried and epidermal sutures.

Many suture characteristics are commonly discussed, including handling, memory, pliability, knot security, tissue reactivity, and others. While there are subtle differences between the handling characteristics of different suture materials, most modern options fall well within the realm of utility, so that while the handling of silk, for example, is clearly superior to the handling of nylon, even nylon handles very well. Similarly, certain materials, such as catgut, may be highly reactive, though the more frequently used formulations, such as chromic gut and fast-absorbing gut, do not lead to enough inflammation to make a marked clinical difference in most situations. For the most part, monofilament sutures lead to less tissue drag, and therefore are useful with running techniques, while braided sutures provide excellent handling and knot security, and are therefore useful for interrupted buried sutures. With improvements in materials, the distinction between outcomes now likely relates more to suturing technique than to choice in suture materials ([Table 6-1](#)).

Table 6-1. Frequently Used Suture Materials in Skin and Soft Tissue Reconstruction

Suture Material Name	Configuration	Handling	Tissue Reactivity	Loss of 50% Strength	Time to Complete Absorption
Absorbable sutures					
Vicryl (polyglactin 910)	Braided, coated	Very good	Moderate	21 days	75 days
Polysorb (glycolide/lactide polymer)	Braided, coated	Very good	Moderate	21 days	75 days
Monocryl (poliglecaprone)	Monofilament	Very good	Moderate	7 days	60 days
Maxon (polyglyconate)	Monofilament	Very good	Moderate	21 days	6 months
PDS I/II (polydioxanone)	Monofilament	Good	Moderate	30 days	6 months
Biosyn (glycomer 631)	Monofilament	Very good	Moderate	21 days	60 days
Caprosyn (polyglytone 6211)	Monofilament	Very good	Moderate	7 days	60 days
Catgut	Braided	Very good	High	Plain: 7 days Chromic: 10 days Fast absorbing: 5 days	Plain: 70 days Chromic: 84 days Fast absorbing: 35 days
Vicryl Rapide	Braided, coated	Very good	Moderate	5 days	42 days
Velosorb Fast	Braided	Very good	Moderate	5 days	42 days
Nonabsorbable sutures					
Monofilament Nylon	Monofilament	Very good	Low		
Prolene, Surgipro (polypropylene)	Monofilament	Good	Low		
Novafil (polybutester)	Monofilament	Very good	Low		
Silk	Braided	Excellent	Moderate		

Absorbable sutures

Vicryl (polyglactin 910)

Vicryl is one of the most frequently used suture materials in skin and soft tissue reconstruction. It is a braided, coated suture material that retains its strength for approximately 3 weeks and is completely absorbed in under 3 months. It has excellent handling characteristics and mild tissue reactivity. Recently, a faster-absorbing variation, Vicryl Rapide, was developed, which loses its strength entirely in under 2 weeks and may be seen as an alternative to fast-absorbing gut suture when suture removal is not desired. An antibacterial-coated variation is now also available on the market (Table 6-2).

Table 6-2. Comparison of Frequently Used Suture Materials from Ethicon and Covidien

Ethicon	Covidien	Application
Vicryl	Polysorb	Standard for buried sutures
Vicryl Rapide	Velosorb Fast	Alternative to fast-absorbing gut; excellent for skin grafts or when suture removal is not an option
Monocryl	Biosyn	Monofilament alternative for buried sutures; support is lost faster than Vicryl/Polysorb
PDS I/II	Maxon	Monofilament alternative for buried sutures; support lasts longer than Vicryl/Polysorb
Prolene	Surgipro I/II	Smooth monofilament nonabsorbable suture; excellent choice for running subcuticular sutures if suture removal is planned
Ethilon	Monosof	Standard nonabsorbable monofilament nylon suture for epidermal approximation

Note: This chart does not imply equivalency; it is designed to outline suture materials that are roughly equivalent in terms of application to skin and soft tissue reconstruction.

Polysorb (glycolide/lactide copolymer)

This is a braided absorbable suture, similar to Vicryl. It provides similar handling and knot security while ostensibly providing slightly improved initial tensile strength when compared with Vicryl. Its absorption characteristics are similar to Vicryl. Velosorb Fast has also been developed as an alternative to Vicryl Rapide.

Monocryl (poliglecaprone)

Monocryl, often seen as a monofilament alternative to Vicryl, is another popular suture material choice. It is more expensive than Vicryl, has excellent handling characteristics for a monofilament suture, and loses its strength in less than 1 month, though complete absorption takes 3 to months. As with Vicryl, an antibacterial option is also now available.

Maxon (polyglyconate)

Maxon is a long-lasting monofilament absorbable suture; while it loses some strength already after 3 weeks, it takes 6 months or more for the suture material to be entirely absorbed, making this a good choice when long-term strength retention may be helpful. It has good handling characteristics, though the slow absorption times should be taken into account if dyed suture material is used, as the suture may be visible if placed in a running subcuticular pattern.

PDS (polydioxanone)

PDS I and II are very long-lasting monofilament absorbable sutures. They are useful when long-term strength retention is critical. PDS II was developed as a better-handling alternative to PDS I, which was criticized for its less-than-ideal handling characteristics. It retains strength for an extended period of time, with 50% strength retention at 5 weeks, and may take more than 6 months to absorb.

Biosyn (Glycomer 631)

Biosyn is another monofilament absorbable suture. It has very good handling characteristics and outstanding initial tensile strength. It retains its strength

for at least 3 weeks and takes up to 4 months to absorb completely. If Biosyn is used for superficial closures, the undyed version may be preferable.

Caprosyn (Polyglytone 6211)

Caprosyn is a fast-absorbing monofilament suture, often seen as an alternative to Monocryl. It absorbs completely in 8 weeks, while retaining tensile strength for 7 to 10 days postoperatively. It is, therefore, useful in low-tension closures, such as those on the face, where rapid suture material breakdown is an advantage.

Catgut

Plain gut is derived from bovine or sheep intestines, and therefore breaks down by enzymatic degradation, rather than the hydrolysis which breaks down synthetic absorbable sutures. Chromic gut is a longer-lasting version of gut, while fast-absorbing gut is heat treated to speed up absorption. On a practical level, fast-absorbing gut may be useful for closures when transepidermal sutures are desired for wound-edge apposition but where suture removal is impractical or inconvenient. Gut does lead to more tissue reactivity than other absorbable sutures and has a tendency toward breakage after multiple passes through tissue.

Nonabsorbable

Nylon

This is a frequently used nonabsorbable suture, and provides minimal tissue reactivity coupled with very good handling. While a very good choice for most closures, it does not move through tissue as smoothly as polypropylene, so if buried subcuticular sutures are placed with nonabsorbable suture, the latter would be preferred. Nylon is available either braided or monofilament; the former may confer slightly better handling, though this is outweighed by the ability of monofilament nylon to move easily through tissue.

Polypropylene (Prolene, Surgipro)

This is a minimally reactive suture that has the ability to move smoothly through tissue. It does have a fair amount of memory, and therefore may be slightly more challenging to work with than nylon. Extra throws are often advisable during knot tying as well, though this does represent a good option for nonabsorbable subcuticular suturing.

Novafil (Polybutester)

This is a very well-handling suture material that also provides significant elasticity. While not as widely used as some other materials, it provides excellent pliability, while the elasticity may be helpful in areas where significant wound edema is anticipated, as it will accommodate tissue swelling while maintaining wound-edge apposition.

Silk

This is the most highly reactive of the nonabsorbable sutures. It also, however, is the gold standard for suture material handling. Its natural softness makes it useful in closures along the lips, where synthetic suture has a tendency to poke against the delicate tissues. Its reactivity, however, makes it less useful on a daily basis for most other surgical sites.

SURGICAL KNOT TYING

Most surgical knots in skin and soft tissue reconstruction are tied using an instrument tie. This is generally the fastest approach and also affords the least amount of suture material waste. Hand tying, using either one- or two-handed ties, may be used rarely in cutaneous surgery and reconstruction.

The distinction in knot tying between transepidermal sutures, where pulling suture tight may lead to strangulation, and buried sutures, where the goal of suture placement is developing directly opposed dermal, muscle, or fascial structures, is critical. When tying a deep suture, it is generally desirable to pull the suture strands together as tightly as possible, secured with a stable knot. For transepidermal sutures, since the goal of suture placement is wound-edge apposition, placing the minimal necessary tension across of the surface of the wound is a must; over-tightening these sutures will lead directly to strangulation, necrosis, and—at a minimum—track mark

formation. Indeed, while dermal suture placement should be performed as tight as possible, transepidermal sutures should be secured with the minimal possible tension, and indeed some additional give may be provided by permitting laxity between the first and second throws of the knot, anticipating tissue edema.

Generally, most surgical knots are tied as square knots, so that the two throws occur in opposite directions, locking the knot in place. Sometimes, a granny knot is desirable, where the first two throws are in the same direction, as this allows the suture material to be cinched down and tightened. It is critical, however, to follow the granny knot with a throw in the opposite direction so that once the knot is in place it is secured and cannot slip.

Each throw refers to one-half knot, i.e. a complete twisting of two strands. Thus to secure a knot, by definition, a minimum of two throws are necessary, and for practical purposes, three throws are used for most braided sutures, while four throws are used for some sutures with a higher risk of knot slippage.

After placement of the suture itself, when beginning an instrument tie the leading end of suture must be grasped with the nondominant hand. In order to minimize the risk of needle-stick injury, it is possible to grasp the suture material approximately 6 to 10 cm from the needle swage between the thumb and index finger of the left hand, allowing the needle to drop down below the hand. Since the needle is hanging freely and is not under tension, there is little chance for a needle-stick injury (Fig. 6-2). Excess suture material may be wrapped around the nondominant hand with a gentle turn of the wrist. Some surgeons prefer to hold the needle itself in the nondominant hand (Fig. 6-3). Recall that when placing a buried suture, the leading and trailing edges of the suture material should be on the same side of the newly created loop prior to initiating a tie.

Figure 6-2. Grasping the suture material during knot tying; the suture material may be looped around the left hand if needed. Note that the needle hangs freely, without tension.

Figure 6-3. Grasping the needle during knot tying.

A single click of the needle-driver locking mechanism is sufficient for locking the needle, and indeed cranking down on the needle driver excessively will result in a loosening of the locking mechanism, leading to inadvertent suture needle slippage in the future. The needle driver may be palmed, where it is locked or released via gentle pressure from the thenar eminence, or may be held with the thumb and the fourth finger (Figs. 6-4 to 6-9). When delicately placing fine-gauge sutures in the face, the body of the needle driver may be held with the thumb, the first finger, and the second finger, and delicately rotated through the skin, permitting precise placement of fine sutures.

Figure 6-4. The basic needle-driver grasping position, with the thumb and fourth finger in the rings.

Figure 6-5. Palming the needle driver. This is the default position for many surgeons. The fourth finger may rest slightly on the inside of the ring.

Figure 6-6. Palming the needle driver with no fingers in the rings.

Figure 6-7. Needle-driver grasping position when performing fine suturing.

Figure 6-8. Holding the forceps for tissue or needle handling.

Figure 6-9. Palming the forceps to free up the fingers for grasping suture material and knot tying.

When grasping the needle body with the needle driver, the default position is to grasp the needle with the end of the needle driver perpendicular to the body of the needle approximately one-third of the distance from the swage where the suture material is bonded to the needle. When first loading a needle, this may be executed by gently pressing the slightly open jaws of the needle driver perpendicularly against the needle and closing the needle driver with a single click. For closures in tight spaces, the needle may be grasped toward the middle or even slightly distally so that the arc of needle placement is relatively shallow, while for other select closures, such as the running subcuticular technique, the needle may be held at an angle relative to the jaws of the needle driver.

Technique for performing an instrument tie with nonabsorbable sutures:

- (a) The leading end of suture material is grasped between the thumb and the index finger of the left hand, approximately 6 cm from the needle swage. The needle driver is brought between the leading and trailing strands of suture, and the leading end of suture is wrapped twice around the needle driver. This should be done by moving the needle driver around the suture, not moving the suture material around the needle driver, as this will permit better precision and economy of movement.
- (b) The needle driver then grasps the trailing end of suture material.
- (c) The hands are pulled in opposite directions, perpendicular to the incised wound edge, so that the right hand moves to the left (where the leading end of suture began) and the left hand moves to the right (where the trailing end of suture began). This should form a surgeon's knot that will be resistant to slippage.
- (d) The trailing end of suture is released by the needle driver, and the needle driver is then brought from the inside, between the two ends of suture, and the leading end of suture is wrapped once around the needle driver.
- (e) The hands again move in opposite directions, so that now the right hand moves to the right and the left hand moves to the left. The knot is now locked.
- (f) For the third (and often final) throw, steps (a) through (c) are then repeated. Additional throws may be placed if needed (Figs. 6-10 to 6-17).

Figure 6-10. The instrument tie for nonabsorbable suture material. Step 1: The needle driver is brought between the leading and trailing strands of suture.

Figure 6-11. Step 2: The suture material is looped twice around the needle driver by rotating the needle driver around the suture material.

Figure 6-12. Step 3: The needle driver is then used to grasp the tail of the suture material.

Figure 6-13. Step 4: The two ends of suture are pulled in opposite directions, perpendicular to the wound, allowing the knot to lay flat.

Figure 6-14. Step 5: The needle driver is then again brought between the ends of suture, and the leading end of suture material is wrapped once around the needle holder, and the trailing tail is grasped.

Figure 6-15. Step 6: The two ends of suture are again pulled apart, now moving in the direction opposite the prior throw, again perpendicular to the wound edge.

Figure 6-16. Step 7: For the third throw, the procedure is repeated again with the needle driver brought between the two strands, the needle driver wrapping the leading end of suture around itself once, the trailing end is grasped.

Figure 6-17. Step 8: The hands are then pulled in opposite directions, pulling the throw tight and securing the knot. For the most braided suture materials, three throws is adequate, while for some monofilament suture, a fourth throw may be added.

Technique for performing an instrument tie with buried sutures:

- (a) The leading end of suture material is grasped between the thumb and the index finger of the left hand, approximately 6 cm from the needle swage. The needle driver is brought between the leading and trailing strands of suture, and the leading end of suture is wrapped twice around the needle driver. This should be done by moving the needle driver around the suture, not moving the suture material around the needle driver, as this will permit better precision and economy of movement.
- (b) The needle driver then grasps the trailing end of suture material.
- (c) The hands are pulled in opposite directions, parallel to the incised wound edge, so that the right hand moves in the direction of where the leading end of suture began, and the left hand moves in the direction of where the trailing end of suture began. This should form a surgeon's knot that will be resistant to slippage.

- (d) The trailing end of suture is released by the needle driver, and the needle driver is then brought from the inside, between the two ends of suture, and the leading end of suture is wrapped once around the needle driver.
- (e) The hands again move in opposite directions parallel to the wound, so that the right hand moves in the direction of where the leading strand began and the left hand moves in the direction of where the trailing strand began. The knot is now locked.
- (f) For the third (and often final) throw, steps (a) through (c) are then repeated. Additional throws may be placed if needed (Figs. 6-18 to 6-25).

Figure 6-18. The instrument tie for absorbable suture material. Step 1: The needle driver is brought between the leading and trailing strands of suture.

Figure 6-19. Step 2: The suture material is looped twice around the needle driver by rotating the needle driver around the suture material.

Figure 6-20. Step 3: The needle driver is then used to grasp the tail of the suture material.

Figure 6-21. Step 4: The two ends of suture are pulled in opposite directions, parallel to the wound, allowing the knot to lay flat.

Figure 6-22. Step 5: The needle driver is then again brought between the ends of suture, and the leading end of suture material is wrapped once around the needle holder, and the trailing tail is grasped.

Figure 6-23. Step 6: The two ends of suture are again pulled apart, now moving in the direction opposite the prior throw, again parallel to the wound edge.

Figure 6-24. Step 7: For the third throw, the procedure is repeated again with the needle driver brought between the two strands, the needle driver wrapping the leading end of suture around itself once, the trailing end is grasped.

Figure 6-25. Step 8: The hands are then pulled in opposite directions, parallel to the wound axis, pulling the throw tight and securing the knot. For most braided suture materials, three throws is adequate, while for some monofilament suture a fourth throw may be added.

Absorbable suture material is generally trimmed either at the knot (for braided suture material) or with a 1- to 2-mm tail of suture, for monofilament suture material. Nonabsorbable sutures are generally left with a 3- to 6-mm tail, depending on surgeon preference, suture material size, and the anatomic location.

When tying knots with nonabsorbable suture, if there is only minimal tension across the surface of the wound, it is sometimes desirable to leave a gap between the initial surgeon's knot and the square not. To execute this

maneuver, the first throw is placed as a surgeon's knot. The next throw is not tightened to lock the surgeon's knot, but rather leaves 1 to 2 mm of space between the surgeon's knot throw and the subsequent throws. This allows for some give so that tissue edema does not cause the suture material to overly constrict the wound edges (Table 6-3).

Table 6-3. Comparison of frequently used reverse cutting needles from Ethicon and Covidien

Ethicon	Covidien
P-1	P-10
P-3	P-13
PS-1	P-14
PS-2	P-12
CP-2	GS-10
FS-1	C-14
FS-2	C-13
P-2	P-21

Note: Comparison does not imply equivalency, as the alloy and finish quality within and between companies will vary. All are 3/8 circle in diameter except the P-2/ P-21 which are ½ circle.

CONCLUSIONS

Historically, much attention has been paid to the various characteristics of suture materials, such as memory and handling, though most modern suture materials are so easy to use that these differences largely become matters of individual taste and preference. High-quality suture material used on a high-quality needle permits the facile placement of the large numbers of suture throws that are common in dermatologic surgery. In general, the choice of needle and suture material gauge, rather than suture material itself, may contribute more to the success of an individual procedure. The most frequent error encountered by novice dermatologic surgeons is using a needle that is too small for a given anatomic location, or using a technique that does not permit the needle to pass naturally and smoothly through tissue. Therefore,

attention to technique, coupled with choice of a sufficiently large needle for the closure in question, may go a long way to optimizing surgical outcomes.

CHAPTER 7 Antibiotics: Preoperative and Postoperative Considerations

Allen F. Shih
Jonathan Kantor

SUMMARY

- The rate of infection after skin surgery is likely between 1% and 4%.
- Antibiotic use in dermatologic surgery has declined markedly over the past several decades, as studies highlighting the baseline low rate of wound infections, coupled with the individual and societal risks associated with widespread antibiotic use, have made the routine prescribing of perioperative antibiotics no longer the standard of care.

Beginner Pearls

- The differential diagnosis of postoperative infection includes irritant or allergic contact dermatitis, suture reactions/suture abscesses, filler reactions (if relevant), and inflammatory chondritis.
- Contact dermatitis should be considered, particularly when topical antibiotics or adhesives were used, or when the involved area is geometric.

Expert Pearls

- Risk factors for infection include patient factors, surgical factors, and surgical site factors.
- One study demonstrated a statistically significant benefit to local intra-incisional clindamycin injection for Mohs micrographic surgery cases; the solution was prepared by adding 0.15 mL of clindamycin (150 mg/mL) to a 50-cc bottle containing lidocaine (1%) with epinephrine (1:100,000) buffered with sodium bicarbonate (5 mL of an 8.4% solution)

Don't Forget!

- Cephalexin or dicloxacillin can be used as prophylaxis for wedge excisions of the lip or ear, flaps on the nose, and grafts.
- Clarithromycin, levofloxacin, TMP-SMX, metronidazole, and ciprofloxacin are associated with a higher risk of hypoglycemia in diabetic patients taking sulfonylurea medications.

Pitfalls and Cautions

- While antibiotics are typically given the hour before the procedure, there is ambiguous data about whether prophylactic antibiotic timing affects the risk of SSI.
- Given the high rate of warfarin and sulfonylurea use in the patient population undergoing dermatologic surgery, systemic antibiotics should be prescribed with extreme caution and an eye to minimizing the risk of drug–drug interactions.

Patient Education Points

- No rigorous study has demonstrated a robust statistically significant benefit to utilizing any single topical antibiotic preparation, and the American Academy of Dermatology has, therefore, warned against the routine use of topical antibiotics after clean surgical procedures as part of its Choosing Wisely campaign.

- Patients often request perioperative antibiotics under the assumption that these will decrease their risk of developing an infection; therefore, adequate education may be valuable in dissuading patients from this practice and increasing their comfort level.
- It may be helpful to explain to patients that bacteremia is more likely after brushing their teeth than it is postoperatively.

CHAPTER 7 Antibiotics: Preoperative and Postoperative Considerations

INTRODUCTION

Antibiotic use in dermatologic surgery has declined markedly over the past several decades, as studies highlighting the baseline low rate of wound infections, coupled with the individual and societal risks associated with widespread antibiotic use, have made the routine prescribing of perioperative antibiotics no longer the standard of care. Dermatologic surgeons must understand the subtleties of antibiotic choice not only to guide clinical patient management, but also to elegantly explain to patients why they would—or would not—benefit from antibiotic use in the perioperative period. An anxious patient can often be easily calmed by providing a reasoned explanation of the scientific basis of the surgeon's decision to decline a patient-suggested antibiotic prescription. Understanding both the scientific literature as well as society-level recommendations regarding antibiotic use is, therefore, useful both for patient care and patient peace of mind.

EPIDEMIOLOGY

The rate of infection after skin surgery is likely between 1% and 4%,^{1–4} varying based on the type of surgery and risk factors for infection. Rates of

infection after Mohs micrographic surgery, excisions, full-face CO₂ resurfacing, and flaps range from 0.7% to 3%; these numbers generally increase with the complexity of the surgical procedure (Table 7-1).⁵ The infection rate for Mohs surgery without prophylactic antibiotics has been reported at under 1%.⁴ There are significant differences in the rates of infection depending on anatomical site and patient risk factors, with repairs on the genitalia, ears, or lower extremities, or in those with other risk factors, such as diabetes, associated with an increased risk of infection.²

Table 7-1. Incidence of Infections in Dermatology Procedures⁵

Incidence of Infections in Dermatologic Procedures	
Procedure	Overall Infection Rate (%)
Mohs micrographic surgery	0.7–2.3
Excisions	1.9–2.3
Full face CO ₂ resurfacing	1.1–7.6
Flaps	3

Data from Shurman DL, Benedetto AV: Antimicrobials in dermatologic surgery: facts and controversies, *Clin Dermatol*. 2010 Sep-Oct;28(5): 505–510.

Despite the low incidence of infections, when they do occur, surgical site infections (SSI) can lead to severe complications.⁶ In dermatologic surgery, serious adverse events occur in only 0.02% of cases, though the rate of postsurgical acute care visits attributed to SSIs in ambulatory surgical centers is around 0.5% in the 30 days after surgery.⁷ Moreover, skin surgery infection rates are likely several-fold higher in developing nations, as the burden of overall healthcare-associated infections in resource-limited settings is three times higher than the infection rates in developed countries.⁸

Surgical site infections—clinical features and diagnosis

SSIs, while generally mild in nature, may lead to severe complications, including bacterial endocarditis and prosthetic joint infection. As defined by

the Centers for Disease Control and Prevention (CDC), SSIs are infection occurring within 30 days of the procedure, involve only the skin and subcutaneous tissue at the incision, and include one of the following four criteria: purulent drainage from the incision site; positive microbiologic testing from an aseptically obtained specimen; presence of pain or tenderness, localized swelling, erythema, or heat; or diagnosis of SSI by a physician (Table 7-2).⁹ SSI typically occurs in the first 2 weeks after the procedure.

Table 7-2. Superficial Incisional Surgical Site Infection Definition from the CDC

Superficial Incisional Surgical Site Infection (SSI)

Within 30 days after operative procedure

(day 1 = procedure date)

Involves only skin and subcutaneous tissue of incision

One of the following:

1. Purulent drainage from superficial incision
2. Positive microbiologic testing (either culture or nonculture test) from aseptically obtained specimen for purposes of clinical diagnosis or treatment
3. Superficial incision that is deliberately opened by surgeon and culture- or nonculture-based testing is not performed

AND

At least one of the following: pain or tenderness; localized swelling; erythema; heat

4. Diagnosis of superficial incisional SSI by surgeon or attending physician

Reproduced with permission from Centers for Disease Control and Prevention (CDC). <https://www.cdc.gov/nhsn/pdfs/pscmanual/9pscscssicurrent.pdf>.

The presentation of SSIs can mimic that of other conditions, and the differential diagnosis may include irritant or allergic contact dermatitis, suture reactions/suture abscesses, filler reactions (if relevant), and inflammatory chondritis. Contact dermatitis should be considered

particularly when topical antibiotics or adhesives were used, or when the involved area is geometric. Suture irritation can lead to suture granuloma/suture abscess formation, essentially a foreign body reaction that provokes local inflammation. However, suture granuloma will be culture negative and occurs only in the areas surrounding the suture material itself. If fillers are used, inflammatory reactions to these foreign materials can produce swelling, erythema, and change in color.¹⁰ Filler-induced complications include dermal nodules, abscesses, or delayed hypersensitivity manifesting as erythematous subcutaneous nodules.¹¹ Detailed patient history can elicit a history of previous soft-tissue augmentation, though patients may not be forthcoming about nonapproved fillers. Biopsy can provide a definitive diagnosis.¹² Finally, in surgical cases involving cartilage, chondritis can mimic SSI with pain, tenderness, and erythema, though it will be culture negative. This is a fairly common phenomenon, as in one study the incidence of inflammatory chondritis after post-Mohs reconstruction was around 5.6%.¹³ The risk of suppurative chondritis, a disfiguring condition involving liquefactive necrosis of the cartilage (particularly involving the ear), can be prevented with perioperative antibiotics with antipseudomonal coverage such as ciprofloxacin.¹³

Delayed reactions should raise the possibility of an infectious process involving biofilms, particularly after procedures involving fillers.¹² Biofilms are polymeric structures produced by bacterial colonies that adhere to surfaces.¹⁴ These self-protective films can thwart normal immune system responses and reduce susceptibility to antibiotics by altering the local microenvironment and employing protective signaling pathways.¹⁵ The NIH estimates that up to 80% of human bacterial infections overall are associated with biofilms. Biofilms are associated with particular bacteria, including *Staphylococcus epidermidis*, *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Escherichia coli*.¹⁵ Bacteria form biofilms upon lack of prompt antibiotic treatment and inappropriate use of steroids and NSAIDs. These biofilms are often culture negative and need to be further investigated with fluorescence *in situ* hybridization (FISH) directed against bacterial DNA.¹⁶

Wound classification and infection risk

Wounds can be differentiated into four types—Class I, Class II, Class III, and Class IV—based on the degree of contamination and inflammation in the wound (Table 7-3).¹¹ Wounds that are clean and uninfected, without any break in surgical sterile technique, show less than 5% risk of infection and do not require antibiotics. Class II wounds are clean-contaminated, including wounds that are intended to heal by secondary intention, and entail a 10% risk of SSI. Class III wounds are contaminated and nonpurulent traumatic wounds with an elevated 20% to 30% risk of infection, requiring antibiotics. Class IV infections include wounds with purulent inflammation or presence of foreign body, which is reported to have an infection risk around 30% to 40% and require antibiotics. Almost all dermatologic surgery wounds are therefore Class I wounds.

Table 7-3. Risk of Surgical Site Infection for Wounds Based on Classes I, II, III, and IV

	Class I	Class II	Class III	Class IV
Label	Clean	Clean-contaminated	Contaminated	Dirty-infected
Description	Uninfected wounds	Entry in oral cavity, axilla, inguinal area	Acute traumatic wounds that are nonpurulent	Purulent inflammation with necrosis, foreign body
Risk of SSI	<5%	10%	20–30%	30–40%
Antibiotics	None	Case-by-case	Antibiotics	Antibiotics

Data from Rossi AM, Mariwalla K. Prophylactic and empiric use of antibiotics in dermatologic surgery: A review of the literature and practical consideration, *Dermatol Surg*. 2012 Dec;38(12):1898–1921.

RISK FACTORS FOR INFECTION

Numerous risk factors impact the likelihood that a patient will develop an SSI postsurgery (Table 7-4).¹⁷ These risk factors can be stratified as patient factors, surgical factors, and surgical site factors. Patient factors include poor nutritional status, immunosuppression, presence of certain comorbidities, concurrent infection, and drug use. Autoimmune diseases, such as rheumatoid arthritis, systemic lupus erythematosus, or drug- or radiation-induced immunosuppression can increase the likelihood of developing a postoperative infection. Concurrent inflammation and infection elsewhere can increase risk of infection as well, and nonemergent dermatologic surgery should be delayed until such conditions are resolved. Comorbidities that increase the rate of SSI include chronic renal disease, peripheral vascular disease, and obesity.¹⁸ Although increased prevalence of comorbidities in older adults may be a confounding factor, increasing patient

age is independently associated with increasing infection risk after dermatologic surgery.^{19,20} While well-controlled diabetes mellitus does not lead to increased risk of wound infections, poorly controlled diabetes results in abnormal glucose levels that increase the risk of wound infections.²¹ Tobacco use is associated with higher incidence of postoperative complications such as wound dehiscence, flap or graft necrosis, prolonged healing time, and infection.²² Wound complications after biopsies occur more frequently in smokers and patients taking corticosteroids.²³

Table 7-4. Risk factors for SSI

Patient	Surgical Technique	Surgical Site
Nutritional status	Complexity (grafts, flaps, wedge excisions)	Ear
Immunosuppression	Hemorrhage	Groin
Concurrent infection	Longer duration	Axilla
Drug use	Multiple stages	Lower extremity
Tobacco use	Poor tissue handling	Nose
Autoimmune disease	Instrument handling	
Radiation		
Renal disease		
Peripheral vascular disease		
Obesity		
Poorly controlled diabetes		
Advanced age		

Surgical risk factors include high degree of surgical complexity, procedures with greater likelihood of hemorrhage, poor surgical technique, long surgical duration, large postoperative surgical defects,² and poor follow-up care. Hemorrhage can lead to local pooling of blood, creating a

suitable local environment for the replication of bacteria. It is important that dermal and subcutaneous defects are minimized with close approximation of edges, as the lack of subcutaneous sutures after excisional procedures has been associated with an increased rate of wound complications.²³ During surgery, crush tissue injury from forceps can predispose to local necrosis and subsequent infection. Moreover, longer duration of surgery, including the multiple stages sometimes required for Mohs surgery, may lead to reduced sterility of the surgical site as the patients transfer between the operating area and the waiting room.⁴ Longer operative times correlate with increased infection rates, with an approximate doubling of risk with each additional hour of surgery. Poor surgical technique and improper instrument handling and sterilization represent additional potential causes of wound contamination.

More complex dermatologic procedures have higher rates of infection than simpler procedures. Punch and shave procedures of the skin not involving mucous membranes do not require antibiotic prophylaxis. While noninvasive laser treatments also do not require prophylaxis, laser resurfacing and other procedures damaging the epidermis on a larger scale can lead to a larger and deeper wound area. More complex procedures, such as grafts, wedge excisions, and flaps are all associated with higher levels of infection risk.²¹ While surgical technique is very important, improper wound dressing and inadequate postoperative care could be a source of infection. Despite these risk factors, it is important to remember that the overall rate of infection in dermatologic surgery remains low.

Surgical site factors refer to the anatomical site of the procedure. Different sites can lead to differing levels of immune defense and can be associated with increased prevalence of bacteria. Lack of perfusion and adequate bloody supply can predispose a surgical site to infection. For example, ear procedures involving cartilage, which lacks an intrinsic vascular supply, are associated with a fourfold higher incidence of wound infection compared to Mohs procedures elsewhere.² Similarly, suboptimal circulation in the nose⁴ and lower extremities, particularly in patients with peripheral arterial disease, may lead to an increased risk of infection.²¹ As the bacterial flora vary by anatomical location, the same surgical procedure can have very different infection rates depending on the surgical site.

Surgical sites in areas below the waist, in the groin, and in areas with many sebaceous glands and hair are associated with increased infection.²¹

Minimizing infectious risk of SSI

Risk of SSI can be reduced through several factors. The National Institute for Health and Clinical Excellence (NICE) recommends that patients should be informed against removing hair from the surgical site and that patients should shower preoperatively to reduce the bacterial population.¹⁸ It is recommended to remove hair with electric clippers with disposable cartridges instead of a razor, because the use of razors may increase infection risk. However, hair removal should be performed when necessary, ideally with scissors.²⁴

Cleaning the surgical site before the procedure can be achieved with povidone–iodine, chlorhexidine, or other surgical scrubs. Appropriately prepped surgical sites have a lower rate of infection, though as 20% of skin bacteria reside deep in sebaceous glands and hair follicles, it is not possible to create an entirely sterile field by topical preparation alone.¹⁸ Still, surgical procedures on prepped skin result in a lower rate of bacteremia than brushing teeth.⁵ Surgical duration should be minimized, as prolonged operating time increases the risk that bacteria may be introduced into the wound. Hands should also be washed prior to the procedure with either alcohol-based hand rubs or aqueous scrubs such as chlorhexidine.²⁵ Current evidence suggests no difference between alcohol-based rubs with active ingredients and aqueous scrubs such as chlorhexidine in the prevention of SSIs, though chlorhexidine-based aqueous scrubs are more effective than povidone–iodine in reducing the number of bacterial colony-forming units on the hands.²⁵

In dermatologic surgery, many procedures do not require true sterile technique, and the majority of studies have not shown any statistically significant difference in infection rate when using nonsterile gloves.^{26–28} Low-cost infection protocols that eliminate the use of sterile gloves during the Mohs procedures, sterile gowns, and sterile half-sheet drapes can be implemented without negatively affecting infection risk.²⁷ Moreover, local

anesthesia itself is bacteriostatic and fungistatic, helping prevent bacterial growth.

Use of prophylactic antibiotics

Use of antibiotics should consider both the putative benefits of antibiotic prophylaxis and the risks and costs associated with the antibiotic use. Except for select circumstances, dermatologic surgery does not require prophylactic antibiotic use. In Mohs surgery, lack of antibiotic prophylaxis does not increase the infection rate.⁴

Goals of antibiotic prophylaxis

The goal of antibiotics is to reduce the risk of SSI, hematogenous joint infections, and infective endocarditis. The mechanism of infection is generally hematogenous dissemination and the development of true bacteremia; the overall incidence of postoperative bacteremia in an immunocompetent and noninfected skin site is below 1%.²⁹ Antibiotics may decrease the quantity of skin bacteria, but infection risk depends on additional bacterial characteristics such as virulence.³⁰ Importantly, the latest guidelines continue to narrow the range of patients appropriate for prophylactic antibiotics. It is important for dermatologic surgeons be aware of new guidelines to avoid the risks of antibiotic overuse and to reserve prophylactic antibiotics for patients deriving maximal benefit.³¹

Risks and costs of prophylactic antibiotics

The costs of antibiotic use include adverse events, drug interactions, financial burden, and societal costs. It is estimated that more than 140,000 visits to the emergency room are attributed to adverse effects of antibiotics annually in the United States, largely from allergic reactions to penicillin and cephalosporins.³²

Drug–drug interactions are a significant concern, as many antibiotics in common use can interact with other medications. For example, certain antibiotics can slightly increase the risk of super-therapeutic warfarin

levels³³ or the risk of hypoglycemia in diabetic patients taking sulfonylurea medications.³⁴ Indeed, clarithromycin, levofloxacin, TMP-SMX, metronidazole, and ciprofloxacin are associated with higher risk of hypoglycemia compared with noninteracting antimicrobials, with an odds ratio between 2 and 4 in older female adults.³⁴ Overall, sulfonamides and clindamycin show the highest rates of emergency room visits per number of outpatient prescriptions, averaging 1 ED visit per 500 prescriptions.³² As antibiotics adversely affect native bacterial flora, prolonged antibiotic treatment increases the risk of acquired antimicrobial resistance.³⁵ As such, unnecessary use of antibiotics contributes to worsening antibiotic resistance.²⁴ Financial costs of antibiotics include the monetary cost for the patient, the cost for treating adverse effects, and the opportunity cost of purchasing and taking the antibiotic.

Antibiotic prophylaxis for infective endocarditis

Antibiotic prophylaxis reduces the risk of infectious endocarditis in patients with high-risk surgical sites or in procedures that involve the mucous membranes such as gingival tissue or oral mucosa.³⁶ Reasons for prophylaxis for infective endocarditis include patient factors such as prosthetic cardiac valves, history of infective endocarditis, cardiac transplant with valvulopathy, patients with cardiac valve repair with recent prosthetic materials or devices, and unrepaired or residual defect after repair of congenital heart disease (Table 7-5).^{11,37} Recent prosthetic repairs consist of repaired defects using prosthetic materials during the first 6 months postoperatively, before the prosthetic material is likely endothelialized.³⁷ Importantly the high-risk category excludes patients with cardiac pacemakers and internal defibrillators, and prophylaxis is not recommended simply due to increased lifetime risk of developing infective endocarditis.³⁸

Table 7-5. High-Risk Patient Characteristics for Infective Endocarditis and Joint Infection

High Risk for Infective Endocarditis

Prosthetic cardiac valves

Hx of infective endocarditis

Cardiac transplant patients with valvulopathy

Patients with cardiac valve repairs with prosthetic materials or device in the past 5 months

Unrepaired congenital heart defect

Repaired congenital heart defect with residual defect

High Risk of Hematogenous Joint Infection

Joint replacement within 2 years of surgery

Hx of prosthetic joint infection, hemophilia, diabetes mellitus, HIV, malignancy, malnutrition, immunosuppression

Immunosuppression with RA, SLE, or drug or radiation-induced

Data from Rossi AM, Mariwalla K. Prophylactic and empiric use of antibiotics in dermatologic surgery: A review of the literature and practical consideration, *Dermatol Surg*. 2012 Dec;38(12):1898–1921.

A Dermatologic Surgery Advisory Statement recommends antibiotic prophylaxis for prevention for infective endocarditis and joint infection only if the procedure occurs on an oral site or site of active skin infection. Any patients fitting these criteria must also satisfy high-risk criteria or have a prosthetic device as defined by the American Heart Association (AHA), American Dental Association (ADA), or American Academy of Orthopedic Surgeons.

Antibiotic prophylaxis for prosthetic joints

The ADA recommends no prophylactic antibiotics prior to surgery for patients with prosthetic joints.³⁹ Previously, patients were considered high risk for hematogenous joint infection if they underwent joint replacement within 2 years of surgery, had immunosuppression or autoimmune disease such as rheumatoid arthritis or systemic lupus erythematosus, or a history of prosthetic joint infection (Table 7-5).^{11,40} In addition, previous guidelines

indicated the need for prophylaxis when the mucosa are penetrated. However, a thorough evaluation of the literature failed to demonstrate a clinically significant association between dental procedures and prosthetic joint infection in terms of effectiveness of antibiotic prophylaxis.³⁹ While the risks of antibiotics seem to outweigh their clinically significant benefits, these identified risk factors should be taken into account, along with physician judgment and patient preferences, to determine appropriate therapy.

Antibiotic selection

Antibiotics should be chosen based on the likely causative pathogens, by considering local skin flora, and keeping in mind patient-specific needs such as allergies and the ability to tolerate oral medications. Wound culture and sensitivities often drive the final selection of the antibiotics. Benefits of antibiotics are weighed carefully against the risks of use. Antibiotics tend to be reserved for specific anatomic sites, complex procedures, and immunocompromised patients.

Skin flora

Skin is colonized by many bacteria, which may vary by anatomical location (Table 7-6).¹¹ Mucous membranes tend to be colonized by *E. coli*, *Streptococcus viridans*, and *Peptostreptococci*. Intertriginous areas are often moist and macerated, predisposing to the growth of *S. aureus* and *Streptococci*. In diabetic patients, streptococcal and coliform bacteria can be found in the perioral area, ear, perineum, and anatomical sites below the waist.

Table 7-6. Bacteria Present in Normal Skin Flora in Various Anatomical Locations

Location	Normal Skin Flora	Pathogenic Bacteria
Glabrous	<i>S. aureus</i> , <i>S. saprophyticus</i> , <i>S. epidermis</i>	<i>S. aureus</i> ^a , <i>S. pyogenes</i> , <i>S. epidermis</i>
Oral or nasal mucosa	<i>S. aureus</i> , <i>Streptococci lactobacilli</i> , <i>corynebacteria</i> , anaerobes	<i>S. viridans</i> , anaerobes (<i>Peptostreptococcus</i>)
Intertriginous	<i>Corynebacterium minutissimum</i> , <i>C. lipophilicus</i> , <i>C. xerosis</i> , <i>C. jeikeium</i> , <i>Acinetobacter</i> spp., <i>S. aureus</i>	<i>S. aureus</i> ^a , <i>E. coli</i> , <i>Enterococcus</i> , <i>Bacteroides</i> , <i>Pseudomonas aeruginosa</i> , <i>Corynebacterium</i> , <i>Candida</i> , <i>Serratia</i>
Sebaceous glands and follicles	<i>Propionibacterium acnes</i> , <i>P. granulosum</i> , <i>P. avidum</i> , <i>Malassezia</i>	<i>S. aureus</i> , <i>Streptococcus</i> , anaerobic bacteria, <i>Pseudomonas</i> , gram-negative species

^a*S. aureus* may be found as a natural resident of the skin.

Adapted with permission from Rossi AM, Mariwalla K: Prophylactic and empiric use of antibiotics in dermatologic surgery: a review of the literature and practical considerations, *Dermatol Surg.* 2012 Dec;38(12):1898–1921.

S. aureus has become increasingly important in terms of both causing severe SSIs and increasing intractability to antibiotic treatment. *S. aureus* is commonly found in the mucosa, including the nasal mucosa (a common colonizing location), oropharynx, and anogenital area.⁴¹ *S. aureus* resistance has become more common, and in severe cases may be associated with mortality rates up to 20%. While MRSA had been separated into those related to health care (HC-MRSA) and community acquired (CA-MRSA), distinctions between HC-MRSA and CA-MRSA are currently much less clinically relevant as the evolution of the bacterial species has led to the loss of epidemiologic distinction.⁴¹ The CA-MRSA clones have been increasingly found in hospital and healthcare facilities⁴² leading to increased concern for healthcare providers, as these highly virulent strains can infect otherwise healthy people.⁴³

Other skin flora include nonbacterial causes such as *Candida* and less common fungal species such as *Cryptococcus*, *Aspergillus*, and *Mucor*, particularly in the immunosuppressed and immunocompromised population. Patients with inflammatory skin conditions such as atopic dermatitis carry different bacterial strains. Prolonged antibiotic use may change local skin flora, just as vancomycin can disturb the natural gastrointestinal flora which secrete antimicrobial peptides and indirectly facilitate the colonization of opportunistic pathogens.⁴⁴ Moreover, low-virulence *Streptococci* are a concern for infectious endocarditis, and *S. aureus* and *S. epidermidis* are a concern for prosthetic joint infections.

With the increased prevalence of antibiotic resistance exemplified by *S. aureus* and the slow development of new antibiotics, it is important to follow strict guidelines to prevent worsening resistance.⁴¹

ANTIBIOTIC SELECTION

In regard to the selection of antibiotics, guidelines are generally derived from the internal medicine and surgery literature, as there are few randomized double-blind studies for antibiotics in dermatologic surgery.¹¹ The choice of antibiotic use in dermatologic surgery is shown in Table 7-7. Cephalexin and dicloxacillin are systemic agents used for prophylaxis on nonmucosal surfaces to cover gram-positive and gram-negative bacteria. Per AHA guideline, *S. viridans* and *Peptostreptococci* can be treated with amoxicillin. For perineal skin, amoxicillin-clavulanate can be selected to combat potential penicillin-resistant organisms. For *Pseudomonas*, fluoroquinolones such as ciprofloxacin can be used. If a culture is obtainable, antibiotics can be selected based on antibiotic sensitivities. Otherwise, antibiotic use can be tailored to the bacteria most commonly found in the local population, the patient risk factors, the surgical site risk factors, and the surgical risk factors.

Table 7-7. Choice of Antibiotics for Prophylaxis in Patients at Risk of Surgical Site Infection

Surgical site	Antibiotic (adult dose)			
	No allergy	Penicillin allergy	Unable to take PO	Unable to take PO with penicillin allergy
Wedge excision of lip or ear, flaps on nose, grafts	Cephalexin or dicloxacillin (2 g PO)	Clindamycin (600 mg PO) or azithromycin/clarithromycin (500 mg PO)	Cefazolin/ceftriaxone (1 g IM/IV)	Clindamycin (600 mg IM/IV)
Groin or lower extremities	Cephalexin or TMP-SMX (2 g PO, double strength) or levofloxacin (1 tablet PO)	TMP-SMX (1 tablet PO, double strength) or levofloxacin (500 mg PO)	Ceftriaxone (1–2 mg IV)	Clindamycin and gentamicin (600 mg/2 mg/ kg IV)

Data from Lee MR, Paver R. Prophylactic antibiotics in dermatological surgery. *Australas J Dermatol*. 2016;57(2):83–91; Wright TI, Baddour LM, Berbari EF, et al. Antibiotic prophylaxis in dermatologic surgery: advisory statement 2008. *J Am Acad Dermatol*. 2008;59(3):464–473.

An Advisory Statement has recommended antibiotic therapy based on the procedure type and anatomical location as well as patient allergies to penicillin or inability to tolerate oral antibiotics (Table 7-7).³⁶ Cephalexin or dicloxacillin can be used as prophylaxis for wedge excisions of the lip or ear, flaps on the nose, and grafts. For those with penicillin allergy, clindamycin or azithromycin can be used, and TMP-SMX or levofloxacin may be used for anatomical sites in the groin or lower extremities. For patients who are unable to tolerate oral antibiotics, parenteral antibiotic therapy can be used. Lastly, for patients who are unable to tolerate oral antibiotics and who have a penicillin allergy, clindamycin can be used and

gentamicin added to cover for the possibility of *P. aeruginosa* infection in the groin or lower extremities.³⁶

Antibiotics are typically given the hour before the procedure. It is thought that this time permits the antibiotic to travel to the surgical site. Parenteral antibiotics are typically given half an hour preprocedure. However, there is ambiguous data about whether prophylactic antibiotic timing affects the risk of SSI.⁴⁵ For longer procedures, the desired duration of action of the antibiotic should be considered. Blood can neutralize some antiseptics as well. For carriers of *S. aureus*, transient decolonization of *S. aureus* from the nasal area can significantly reduce the infection rate, and the use of topical mupirocin–chlorhexidine reduces the infection rate by half.^{24,46}

For SSI, wound culture, microscopy, and antibiotic sensitivities should ideally be performed, and antibiotics should be tailored based on the sensitivities.

Topical antibiotics

Postoperative topical antibiotics are not recommended for routine dermatologic surgery cases.⁴⁷ Numerous studies have evaluated whether the use of topical antibiotic ointment in the postoperative period is associated with a reduction in the already very low baseline risk of SSI in dermatologic surgery procedures, and results have generally suggested that for the majority of wounds, the use of topical antibiotics does not confer a significant advantage. A wide range of topical antibiotic preparations have been explored, including fusidic acid,⁴⁸ gentamicin,⁴⁹ mupirocin,⁵⁰ tobramycin–dexamethasone (combination preparation),⁵¹ bacitracin,^{52–54} neomycin–polymyxin (and in combination),⁵³ and chloramphenicol.⁵⁵ No rigorous study has demonstrated a robust statistically significant benefit to utilizing any single topical antibiotic preparation, and the American Academy of Dermatology has, therefore, warned against the routine use of topical antibiotics after clean surgical procedures as part of its Choosing Wisely campaign.

The use of topical antibiotics may confer a risk to patients as well, since neomycin (11%) and bacitracin (8%) are the two most common causes of allergic contact dermatitis in a general patch-tested US population.⁵⁰

Inflammation risk may similarly be higher in patients treated with topical antibiotics rather than petrolatum.⁵⁶

While the routine use of topical antibiotics is inadvisable, selected surgical sites at increased risk of infection may benefit from the use of topical antibiotic therapy. One study examining the infection rate in a tropical Australian region found that a single dose of topical chloramphenicol (a topical antibiotic rarely used in the United States but popular in the United Kingdom and elsewhere) resulted in a statistically significant reduction in wound infection rate.⁵⁵ That study, however, evaluated wounds that were treated by general practitioners in Australia with a baseline infection rate in the control group of 11%, surgical sites that were possibly prepped with normal saline, and wounds that were closed with a single layer of nonabsorbable sutures; therefore, the generalizability of these findings to the generally low-risk dermatologic surgery population is unknown.

While there is little evidence to support the practice, many dermatologic surgeons—while eschewing the blanket use of topical antibiotic ointment in all surgical cases—will use these agents on select high-risk cases. Thus, wounds on the ears, nose, genitalia, lower extremities, and some flaps may benefit from the use of topical antibiotic preparations. In the United States, mupirocin is generally favored for its broad coverage and lack of significant risk of contact dermatitis. The effect on wound care compliance of providing patients with a prescription topical ointment has not been explored, though this may arguably represent an additional benefit of topical antibiotic use in select cases. As noted above, intranasal topical mupirocin may be useful preoperatively in order to temporarily decrease the nasal carriage of staphylococcal species.

Intrainscisional antibiotics

Local injection of antibiotic formulations in the perioperative period has been investigated for dermatologic surgery. While local injection of aminoglycosides may be helpful to reduce the infection risk on open fractures,⁵⁷ one challenge in dermatologic surgery remains the vanishingly low baseline rate of SSI, making any effect challenging to detect in a clinical trial setting.

One study demonstrated a statistically significant benefit to local intraincisional clindamycin injection for Mohs micrographic surgery cases.⁵⁸ This work was follow-up to an earlier report on the use of intraincisional nafcillin.⁵⁹ The solution for intraincisional clindamycin use was prepared by adding 0.15 mL of clindamycin (150 mg/mL) to a 50-cc bottle containing lidocaine (1%) with epinephrine (1:100,000) buffered with sodium bicarbonate (5 mL of an 8.4% solution). The authors noted that the solution retained its bactericidal properties for at least 1 month after preparation; given the low cost of clindamycin, it has been advocated as a reasonable approach in select patients and wounds. While this approach is not used broadly for all surgical cases, it may be a useful adjunct for wounds or patients at elevated risk of developing SSI.

CONCLUSIONS

Antibiotic use is a critical part of dermatologic surgery, though *appropriate* antibiotic use remains a significant challenge facing surgeons and patients. Given the low baseline SSI risk for most dermatologic surgery procedures, antibiotics—whether oral, topical, or intraincisional—are not routinely prescribed. For higher-risk surgical sites or patients with significant risk factors, however, antibiotics may play an important role in decreasing an elevated infection risk. In cases of active infection, antibiotic use, ideally guided by culture and sensitivity results, is warranted. All true abscesses, while rare, require drainage in addition to antibiotic treatment.

CHAPTER 8 Photography and Digital Technology in Dermatologic Surgery

Jonathan Kantor

SUMMARY

- Three fundamental physical principles govern photography: aperture size, shutter speed, and film speed (ISO).
- Framing and composition are critical aspects of photography; traditional approaches to photographic composition, such as the rule of 3's, do not apply to most photography for surgical dermatology where the area of interest is generally centered in the frame.

Beginner Pearls

- Camera choice should not be dictated by the number of advertised megapixels.
- Lens type and lighting have a far greater impact on photograph quality than resolution.
- Archiving and organizing photographs is an important component of digital photography, and developing a systematic approach to both image capture and storage ultimately results in a more productive and professional environment.

Expert Pearls

- Recent ISDIS recommendations included lighting type (broad spectrum, even illumination, possibly tangential) background color (solid, blue or black colors preferred), field of view (centering the target), orientation, focus/depth of field, resolution (to include hair follicles on regional images and skin texture on close-up images), scale (there some debate regarding whether this is of value), and image storage quality.
- Instead of using specialized photographic equipment, standalone LED worklights may be purchased at a home improvement store.

Don't Forget!

- All images should be saved at the highest-quality setting available on the device.
- Head- or body-mounted video recording devices are very sensitive to slight body movement by the surgeon and may introduce significant camera shake, which is undesirable.

Pitfalls and Cautions

- Ideally, data should be stored on an encrypted drive. Encryption options are built-in to both Apple (using Filevault) and Windows (using Bitlocker) computers.
- All photographs should be taken from the same angle and should include the same amount of surrounding skin in the field; this allows the viewer to see only the surgical procedure as the rest of the image is held constant.

Patient Education Points

- Dermatologic surgeons involved in education and publishing may wish to have all patients sign a blanket photography consent and release so that there is no question after the fact regarding whether individual images can be used.
- When possible, identifying information should not be captured in a photograph unless doing so is necessary.
- Patients may be reassured that all images will be stored in an encrypted format.
- A separate social media release may be helpful if images are to be shared publicly.

CHAPTER 8 Photography and Digital Technology in Dermatologic Surgery

INTRODUCTION

Dermatologic surgery is a visual field. Preserving a visual rendition of a particular disease entity, biopsy site, surgical technique, or surgical outcome is a critical part of the dermatologic surgeon's practice.

The advent of the printing press in 15th-century Europe changed the medical landscape, as the written word could efficiently and (relatively) inexpensively be transmitted to others around the world.

Nineteenth-century dermatology texts, such as Robert Willan's *On Cutaneous Diseases*, and Pierre Louis Alphonse Cazenave's *Maladies de la Peau* relied on hand-drawn color plates to convey the subtleties of clinical conditions.

Moulage, the three-dimensional (3-D) wax models designed to convey—in sometimes haunting detail—the appearance of particular skin diseases, were frequently used in teaching centers of 19th-century France and later around the world.¹ In the late 19th and early 20th centuries, stereoscopic cards came into vogue and were used widely for dermatologic education, particularly for explaining basic skin conditions to generalist physicians.²

The advent of low-cost photography led to a sea change in dermatologic education, as the democratization of dermatologic education increased at a logarithmic rate. Indeed, it was no longer necessary to study with a master

clinician or in a major center to be exposed to a wide array of skin diseases, since every budding dermatologist could be exposed to accurate high-fidelity images of a variety of diseases of the skin.

In dermatologic surgery, a similar transition took place over the latter part of the 20th century, as photography—and, more recently, videography—permitted the sharing of information, techniques, and approaches around the world. Indeed, the rise of dermatologic surgery as field can in some ways be seen as the product of the democratization of closely held techniques.

PHOTOGRAPHY

For practical purposes, all photography in dermatologic surgery today is digital photography; while film photography may be used on occasion; this is generally done for artistic, rather than practical, purposes.

Fundamentals of photography

While most dermatologic surgeons can easily accomplish all skin photography with a simple point-and-shoot camera—or even a smartphone camera—a basic understanding of the principles of photography remains helpful.

Three fundamental physical principles govern photography: aperture size, shutter speed, and film speed (ISO). The interplay between these physical components of a photograph has the potential to significantly affect the quality and value of a photograph (Fig. 8-1).

Figure 8-1. The relationship between aperture (**top row**), shutter speed (**middle row**), and film speed/ISO (**bottom row**). Note that with larger apertures (smaller f-stops) there is a markedly reduced depth of field.

The aperture is a measure of the size of the opening that allows light to enter the camera and come into contact with the CCD array, and is inversely related to the f-stop number. There is a tradeoff between aperture size and depth of field; larger apertures (smaller f-stop numbers) permit more light to enter the lens, and thus permit a faster shutter speed and crisper image. This also results in a shallower depth of field, where only portions of an image may appear to be in focus. This is a particular problem when taking macro photographs of structures with significant 3-D variability, such as the nose. The use of a powerful and consistent flash, as well as a steady hand or tripod, may partially make up for this tradeoff and permits smaller aperture sizes for these images.

Framing and composition are critical aspects of photography; traditional approaches to photographic composition, such as the rule of 3s, do not apply to most photography for surgical dermatology where the area of interest is generally centered in the frame.

White balance is usually performed automatically with most modern cameras; for most applications in dermatologic surgery, this is more than adequate.

Most dermatologic surgeons use an automatic focus setting, whether on a point-and-shoot or single-lens reflex camera. Manual focus options allow increased control, but concomitantly introduce a significant potential for operator error. Many cameras offer several options for automatic focus;

since dermatologic surgery photography usually relies on a centered image of interest, autofocus using a central point may work best for this application.

Standardization

The Digital Imaging and Communications in Medicine (DICOM) standards are used for specialized medical imaging such as that performed by radiologists. In dermatology, given the wide availability of consumer-level imaging equipment, the DICOM standards are typically not used.³ Recently, the International Society for Digital Imaging of the Skin (ISDIS) proposed a new set of standards for dermatology imaging that address many of quality and generalizability concerns regarding skin photographs.³ These should be understood within the context of similar proposals by a number of other potential stakeholders, such as the American Telemedicine Association.

The recent recommendations included a discussion of lighting type (broad spectrum, even illumination, possibly tangential) background color (solid, blue or black colors preferred), field of view (centering the target), orientation, focus/depth of field, resolution (to include hair follicles on regional images and skin texture on close-up images), scale (there some debate regarding whether this is of value), and image storage quality.³

Camera selection

With quality improvements in smartphone and tablet cameras, almost all dermatologic surgery images today can be adequately captured on simple point-and-shoot, smartphone, or tablet cameras. For dermatologic surgeons who plan to publish photographs or perform clinical studies, D-SLR (digital single-lens reflex) cameras with interchangeable lenses and a dedicated flash system may be helpful.

The resolution available in even smartphone cameras exceeds that needed for almost any application in dermatologic surgery. Therefore, camera choice should not be dictated by the number of advertised megapixels.

D-SLR cameras are often chosen not because of their resolution, but because they have the ability to work with a range of lens types and flash systems. Ultimately, lens type and lighting have a far greater impact on photograph quality than resolution. Therefore, all else being equal, a D-SLR

with a 5-megapixel resolution is far superior to a point-and-shoot camera with a 25-megapixel resolution.

A 60-mm or 100-mm macro lens is helpful for close-up photography, and may be used for standardized photographs. Classically, dermatologic surgeons have advocated using sidelighting. An LED ring flash, however, is very effective at standardizing lighting between photographs. Since dermatologic surgery photographs benefit from overall high-quality lighting, rather than the focus on skin texture that is important when recording medical dermatology photographs, a ring flash is often very useful.

All-in-one photographic systems are available from several manufacturers, although their adoption is limited by their significant cost and marginal improvement over using standardized poses and equipment; thus, their use is largely limited to clinical trials and some academic centers.

File sizes and formats

Even the best photographer composing ideal images with an outstanding camera will not be able to convey quality images if they are not saving their files appropriately. Smartphone, tablet, and point-and-shoot cameras are all able to record at a range of quality settings. As a general rule, all images should be saved at the highest-quality setting available on the device, as images can always be compressed at a later date if needed. Taking a few moments to set up the camera appropriately with the highest-quality settings is an excellent time investment.

For D-SLRs, additional options are often available. Most cameras permit the user to save files in RAW format (the highest quality available) as well as one of many compressed formats. One useful approach is to set the D-SLR to record *both* RAW and highest-quality (largest) JPEG (or other compressed) formats; if significant adjustment will not be needed, the JPEG images can be used for almost every application, while the RAW images can be manipulated if needed without impacting file quality.

Occasionally, reference is made to the distinction between *lossless* and *lossy* compression. The former allows digital images to be compressed but (as the name implies) does not result in any loss of image data (e.g., TIFF). The latter leads to much more dramatic compression—and hence smaller file sizes—but also results in a decrease in data included in the image (e.g.,

JPEG). That said, for all practical purposes most JPEG images are more than adequate for any application in dermatologic surgery.

For video, many smartphones now record at 4K resolution, far higher than can be appreciated except on the largest screens—or unless single frames are teased out or images are significantly zoomed. Therefore, resolution is no longer the quality-limiting step in video recording. By definition, the smaller lenses on smartphones have only a fraction of the light-capturing ability of large D-SLR cameras or dedicated video equipment, though with appropriate lighting and stabilization, as well as simple postproduction quality improvement, they can provide quality rivaling that seen using professional-grade equipment.

Video should be recorded in a standard format and retained at the highest-quality setting available. The cost of digital storage continues to plummet, and quality video should never be compromised simply to save storage space.

When preparing to publish photographs in print, the number of dots per inch (DPI) is often used as a measure of quality. As a general rule, high-gloss print publication should use images that are saved at 300 DPI; this is far greater than the 72 DPI that is standard for on-screen presentation. Of course, the number of DPI must be interpreted in concert with the overall size of the image—the number of pixels that are included horizontally and vertically.

HIPAA compliance

The Health Insurance Portability and Accountability Act (HIPAA) defines personal health information (PHI) as “individually identifiable health information transmitted or maintained” by any covered entity. Thus identifiable photographs fall under this rubric, assuming that they can be reasonably connected to the person in question. Full-face photographs certainly fall under this definition, and many photographs with minimal editing, such as the black bars over the eyes that were once popular for de-identification, also may remain identifiable. Moreover, other features, such as unique or identifying tattoos, may raise the specter of HIPAA protection even if no facial features are present.

It is always best to err on the side of caution regarding de-identification and compliance; thus, when possible and feasible, partial-face photos, rather

than full-face photos, may be used.

Most importantly, however, patient consent for recording their identifying photographs as well as potential uses for the photographs should always be sought. In practice, active dermatologic surgeons involved in education and publishing may wish to have all patients sign a blanket photography consent and release so that there is no question after the fact regarding whether individual images can be used. It is often easier to explain to all patients that their photos may be used; for those few patients who refuse (generally a small minority), their charts can easily be flagged to ensure that photographs are not taken.

Ideally, data should be stored on an encrypted drive. Encryption options are built-in to both Apple (using Filevault) and Windows (using Bitlocker) computers. Removable media, such as external hard drives or USB sticks, may also be easily encrypted using built-in software. Encryption is particularly valuable for laptops, as a stolen laptop with PHI may represent a significant security breach. If the laptop is encrypted, however, the data remain secure and no HIPAA violation will have occurred. One recent study has addressed the marked variability in approaches by Mohs surgeons to storing digital photographs.⁴

Video capture

Video is a useful adjunct for patient education, and is also helpful when teaching residents, students, and colleagues. Several simple steps may be helpful when attempting to capture effective video.

First, as with still photographs, minimize distractions within the frame; the video and audio should include any necessary features being conveyed while excluding distracting background. For example, video of a surgical procedure should include the entire surgical site from either the surgeon's perspective or directly overhead, ideally with a small margin of blue or green drape around the periphery. Even for practices that generally rely on disposable fenestrated drapes for surgical procedures, it may be worthwhile to use cloth drapes for recorded surgical procedures given the overall aesthetic improvement.

Second, audio voiceovers may be useful, particularly when the goal of the video is largely didactic. This can be accomplished either from directly

within freely available video editing software or using specialized audio editing software. A USB-based condenser microphone may be a good investment if significant audio recording is anticipated.

Third, lighting is probably the greatest contributor to video quality; surgical video recording can be performed ideally using a set of two white light LED arrays. Instead of using specialized photographic equipment, standalone LED worklights may be purchased at a home improvement store. Avoid using head-mounted LEDs, as these create a small bright focus of light that may wash out the remainder of the image.

Fourth, video recording is dependent on the steadiness of the camera. In general, a tripod works well, and for overhead video recording a perpendicular arm may be added (and is included with some tripods) for better stabilization and a bird's eye view of the procedure.

Head- or body-mounted video recording devices are popular in action sports and are used by some dermatologic surgeons. The disadvantage of these approaches is that the mounts are very sensitive to slight body movement by the surgeon and may introduce significant camera shake, which is undesirable.

Approaches to skin photography

Facial photography

Standardized poses are very useful in photography for dermatologic surgery. For facial procedures, a set of three photographs is often sufficient: the anterior–posterior view, oblique view, and lateral view ([Fig. 8-2](#)). For nasal reconstruction, a base view may be helpful as well to assess alar asymmetry.⁵

AP View:

- Align pupils and top of ears
- Make sure you can see base of nostrils

Lateral View:

- Align lateral canthus and top of ear
- Align brow ridge and chin
- Should not see the contralateral brow or philtrum

Oblique View:

- Align pupils and top of ears
- Tip of nose should line up with the zygomatic arch on the contralateral side

Figure 8-2. A photography guidelines sheet for use in the office setting. (Based on Martinez JC. Standardized photography in facial reconstructive surgery: clinical pearls to simplify a complicated task, *Dermatol Surg.* 2011 Jan;37(1):82–85).

Capturing images using standard poses permits better before-and-after comparisons and more meaningful and intuitive photographs.

For all photographs, patients should be looking straight ahead with a neutral expression. A plain-colored background is ideal, and this can be easily accomplished with either a colored backdrop placed on the back of each examination room door or the use of a neutral paint color on the examination room walls.

Body photography

For photographs of the trunk and extremities, standardized angles and poses have been proposed by the American Society for Dermatologic Surgery. These are most useful for cosmetic procedures, when documenting the degree of improvement seen after an interventional procedure is useful. The regional photographs can also be used for surgical site photography, though the images may need to be zoomed in significantly to be meaningful.

Surgical site photography

For surgical procedure on the head and neck, standardized poses may be useful for recording outcomes and evolution over time. Some surgical procedures may also benefit from close-up photographs of the surgical site, in which case variations of the standardized poses may be recorded. Alternatively, if high-resolution imaging is used, photographs may be zoomed and cropped after the fact.

Next to a well-composed high-resolution photograph with minimal distractions, the next most important priority for surgical site photography is consistent angle and perspective. All photographs should be taken from the same angle and should include the same amount of surrounding skin in the field; this allows the viewer to see only the surgical procedure as the change as the rest of the image is held constant.

For educational purposes, step-by-step photographs are often useful as well. In these cases, either an overhead or over-the-shoulder perspective is most useful, as it permits the viewer to intuitively understand the procedure and identify with the surgeon's movements.

Photography has also been used for Mohs map creation.⁶⁻⁸ Particularly for large or complex cases, the Mohs map can be overlaid on a printout of a digital photograph. This may assist with accurate map creation and is also useful in the unlikely event that a patient will need to be referred on for adjuvant treatment.⁶ Fully digital Mohs maps may be useful as well, as these do not require printing of photographs and are easily shared in an electronic medical record system (Fig. 8-3).

Figure 8-3. A fully digital Mohs map.

Photography for biopsy-site identification

Biopsy-site identification is of critical importance, as wrong-site surgery has potentially serious consequences for both patient and surgeon. Indeed, wrong-site surgery is one of the most common and serious adverse events identified by the Joint Commission,^{9–12} and one of the most common causes of medical malpractice cases against Mohs surgeons.¹³ As many as one-quarter of patients may not be able to correctly identify their biopsy site.¹⁴

Dermatologic surgeons frequently use photography to record biopsy sites. Importantly, biopsy-site photography must include sufficient local landmarks to identify the location adequately. Thus macro photographs of the lesion of interest, if taken, should be supplemented with regional photographs that are self-explanatory with respect to site identification. Ideally, biopsy-site photographs would be included in a patient's electronic medical record, though this may be limited by practical and privacy considerations. Biopsy-site photographs are particularly useful when patient and surgeon do not immediately agree on the identification of the putative biopsy site.

Recently, patient-recorded biopsy-site photography has been explored as an adjunct approach to biopsy-site identification.¹⁴ The advantage of this

approach is that it does not require any HIPAA protection or data protection on the part of the surgeon, as the patient is responsible for storing their own photographs. This is also, however, its chief pitfall, as the surgeon is then reliant on the patient to bring their images to the visit; the worst-case scenario would be a patient who fails to bring their images to the surgical appointment and verbally confirms a biopsy site, only to later revise this decision based on newly discovered photographs. Some limitations of patient-recorded biopsy-site photographs include the tendency to excessively zoom and to take photographs that are out of focus.^{9,14} An approach using a separate photographer has been suggested as a solution to some of these quality concerns.⁹ Skin self-photography may be useful for dysplastic nevus monitoring,¹⁵ though the consequences of a forgotten or lost image or set of images are potentially greater when this approach is used for biopsy-site recording. Using a standalone iPod that is encrypted and not connected to the internet is a simple solution to this common problem, as the device is inexpensive, portable, and is easy to search when a patient returns and the biopsy site must be identified. Since the same device both records and organizes the photographs, it significantly reduces the need for staff time investment.

Postoperative monitoring

The widespread use of smartphone digital cameras has led to the investigation of their use for postoperative wound monitoring.^{16,17} Studies have examined patient satisfaction associated with taking photographs and using a mobile application to communicate with the surgeon and support staff. As with chronic wound management, patients appear to be largely enthusiastic regarding the possibility of engaging in remote wound monitoring.

Telesurgery consultation

Surgical consultation may take place with the assistance of teledermatology techniques. The American Academy of Dermatology has guidelines in place regarding teledermatology consultation, and advocates that physicians establish a true physician–patient relationship prior to a teledermatology

consultation.^{18–22} Given the limitations of this approach coupled with the feasibility of same-day consultation for most Mohs surgical procedures, this is rarely needed in practice. Still, it remains a useful adjunct in the event that a patient or referring physician expresses a preference for a consultation prior to the day of surgery.

OTHER TECHNOLOGY APPLICATIONS

Several other technologies have been explored for use in the dermatologic surgery setting, though their adoption, at this point, has yet to become widespread. Many of these approaches are used widely for research and are in the development stage for practical daily use in the dermatologic surgery practice. Widespread adoption will depend in part on ease of use as well as financial considerations.

Reflectance confocal microscopy permits *in vivo* analysis of human skin, with resolution rivaling that of traditional histopathology. Until recently, this technology was limited by the learning curve associated with interpreting the grayscale images; over the past decade, digitally stained mosaic images have become available that mimic the colors and shapes seen with traditional histopathology.^{23–30} This represents a major step forward in potentially broadening the use of this approach, as posttraining interobserver agreement was found to be 98%. A multimodal microscopy approach has been developed using acridine orange fluorescence, eosin fluorescence, and endogenous fluorescence to image cellular nuclei, cytoplasm, and extracellular components, respectively.²³ This approach permits confocal microscopy to be used not only for basal cell carcinoma, but squamous cell carcinoma detection as well. A more rapid, and therefore potentially more clinically useful, approach has been developed using high-speed strip mosaicing confocal microscopy as well.^{30,31}

Optical coherence tomography is another *in vivo* real-time imaging technique that can be used for diagnostic purposes. As with confocal microscopy, it has been used for diagnosing basal cell carcinoma. While this technology may increase the diagnostic accuracy of a clinical examination,³² it is also imperfect, and indeed one case of amelanotic melanoma was misdiagnosed as basal cell carcinoma in an Australian study.^{33,34} Dynamic

optical coherence tomography may overcome this limitation, though further research and product development need to occur.^{35,36} Therefore, while this technology holds significant promise for the future, traditional histopathology remains the gold standard.

Other technological approaches that have been explored include the use of head-mounted camera and computer systems such as Google Glass,^{37,38} the use of infrared thermal imaging, and the use of 3-D imaging and cameras,³⁹ as well as 3-D scanning devices (Fig. 8-4).^{40–42} Near-infrared imaging of vascular structures is also available, though these devices are severely limited by their limited applicability to dermatologic surgery and significant upfront cost. While all of these approaches may be valuable, they have yet to be widely adopted in dermatologic surgery.

A

B

C

Figure 8-4. The next generation of three-dimensional imaging. Data may be acquired with a variety of technologies, including a structured light sensor or stereophotogrammetry in order to create a solid model (A), a colorized three-dimensional image (B), or an overlay with a three-dimensional mesh (C).

CONCLUSIONS

Photography is now an integral part of the practice of dermatologic surgery. On a practical level, training office staff to record photographs using standard poses and positions is a worthwhile effort, and results in images that are consistent and reproducible. Archiving and organizing photographs is an important component of digital photography, and developing a systematic approach to both image capture and storage ultimately results in a more productive and professional environment.

CHAPTER 9 Ethics in Dermatologic Surgery

Jonathan Kantor

SUMMARY

- Ethical action, like informed consent, is a process.
- Most ethical challenges occur when there are conflicting principles, conflicting duties, or conflicting concepts of to whom the greatest—or least—ethical allegiance is owed.

Beginner Pearls

- For centuries, philosophers have struggled with the distinctions between ethics, morality, law, and—more recently—professionalism.
- Ethics reflects a social imperative that is based on moral underpinnings; ethics can therefore be conceptualized as morality in action.

Expert Pearls

- Professional morality may be broader and deeper than common morality, as it addresses the moral expectations for a particular group.
- Principlism, perhaps the most popular ethical framework, relies on the (equally weighted) principles of autonomy, beneficence, nonmaleficence, and justice. These four principles are frequently used as a litmus test for ethical legitimacy.
- Morality is a social institution, and the common morality represents the core group of morals that are considered universally binding.

Don't Forget!

- Other approaches to ethical decision-making abound, including utilitarianism, aspirational ethics, casuistry, deontological approaches, rights theory, and virtue ethics.
- While cosmetic dermatology patients may interact with physicians as if they are *consumers*, rather than *patients*, they should still be treated as the latter.

Pitfalls and Cautions

- Keep in mind that there is often more than one reasonable solution to an ethical quandary.
- An action can be legal without being ethical and ethical without being legal.
- Body dysmorphic disorder is a common condition, and identifying such patients is an important challenge for the cosmetic dermatologist, not least because the patient is likely to be dissatisfied after *any* intervention.
- The need for a consistent ethical framework led to the expansion of principlism to the point that the four principles are frequently used as a litmus test for ethical legitimacy, though the challenges of this model of applied ethics may be substantial.

CHAPTER 9 Ethics in Dermatologic Surgery

INTRODUCTION

Appreciating and understanding the fundamentals of bioethics is of significant importance for dermatologic surgeons, both in order to better assess and evaluate the nature of ethical challenges and to better engage in informed ethical decision making. The epistemology of bioethics—how we know what falls within the boundaries of ethical actions and what does not—is worth exploring not simply as an intellectual exercise, but as a stepping stone to expanding our understanding of *why* a particular act is or is not the appropriate choice in any given situation.

Despite a 200-year trend of codifying ethical and professional mores, the subjective nature of morality and ethics may be challenging, particularly for physicians whom, as scientists, expect an objective and standardized system rather than a relativistic amalgam of duties and principles.

Ethical challenges may be of several varieties. Sometimes, a true moral or *ethical* dilemma is present, while at others the central challenge is a *practical* dilemma, where a sense of ethical obligation conflicts with either self-interest or pragmatic considerations. Most ethical challenges occur when there are conflicting principles, conflicting duties, or conflicting concepts of to whom the greatest—or least—ethical allegiance is owed.

Ethical action, like informed consent, is a process. Indeed, the very act of expressing concern regarding the ethical implications of an action constitutes a significant step in the right direction, as even professional ethicists may disagree regarding the ideal course of action in complex ethical cases. Real-

world ethical challenges generally occur when various ethical imperatives are perceived as being in conflict, or when various duties, and those to whom the dermatologist is responsible, appear to conflict.

HISTORY

Ethics has been a subject of discussion, debate, and deliberation for thousands of years. While the nascence of ethical and moral theories is often ascribed to ancient Greek philosophers, Mesopotamian writings and codes of law—as well as ancient Greek epic poems significantly predating the development of true Greek philosophy and the Old Testament itself—address fundamental ethical issues.¹ Subsequent ancient Greek philosophical writings, particularly those of Plato and Aristotle, formally codified a system of ethical thought.²

In ancient Greece, Socrates spoke at length of fundamental principles that would today be considered utilitarian, with a focus on creating the greatest good.^{3,4} Aristotle is often considered the father of modern ethics, with his focus on eudaimonia; to Aristotle, appreciating the nature of ethics was a prerequisite to leading the ideal flourishing life.^{5–10}

The origins of bioethics as a distinct field of inquiry may be traced to the 1770 publication of John Gregory's *Lectures on the Duties and Qualifications of a Physician* and the subsequent 1803 publication of Thomas Percival's *Medical Ethics* (Fig. 9-1).^{11–14} In Percival's code—later used as a model for the American Medical Association's (AMA) first *Code of Ethics*—he reviewed the ethical underpinnings of practice and duty in an organized fashion. It is no surprise that this occurred in the context of the industrial revolution and rapid developments in the field of medicine, when medical care had shifted from a Galenic worldview to a proto-scientific approach to inquiry.¹⁵ Suddenly, the physician had a greater role to play in decisions that could reasonably have a major impact on the patient's life. Moreover, in the post-enlightenment period, the desires of the patient as an individual also took on a more important role. Further, as society evolved from a medieval feudal system to the beginnings of the modern industrialized world that we know today, obligations—between worker and employer, citizen and country, and physician and patient—took on a more urgent role.¹⁶

Finally, in the United States in the 1820s, with new world medical education still in its infancy, physicians turned to self-regulation in an attempt to staunch the pressure from charlatans who were felt to be unfairly charging and improperly treating their unwitting patients.¹

Figure 9-1. First edition of Thomas Percival's medical ethics.

Modern warfare also impacted the perceived need for a robust grounding in medical ethics. From the bloody US Civil War to the trenches of the First World War and the mass slaughter of the Second World War, the very tools of industrialization that were lauded as harbingers of a truly brave new world were used to take military and civilian lives on a previously unimaginable scale.

With this backdrop, it is no surprise that ethics in medicine took on an even greater urgency in the 20th century. From Tuskegee to Josef Mengele, physicians—long lauded as working in their patients’ best interests—were suddenly seen, as industrialization was in the centuries before, to represent a powerful force that could as easily harm as help.

Ethics, law, morality, and professionalism

For centuries, philosophers have struggled with the distinctions between ethics, morality, law, and—more recently—professionalism. Morals, or common morality, represent a set of behaviors, actions, and imperatives that are so broadly understood to be true that they have been accepted as fundamental and universal. Horace noted over 2,000 years ago that laws without morals are useless,¹⁷ and indeed while moral laws are desirable, only a fraction of moral actions are enumerated in law. Morality, therefore, is a social institution, and the common morality represents the core group of morals that are considered universally binding.

The common morality encompasses not only a set of obligations (do not kill, do not steal), but also a group of ideals and virtues (be charitable, help others when possible). These morals are universally accepted within a society, and their acceptance is often considered a precondition for entry and societal acceptance.¹⁸

Ethics reflects a social imperative that is based on moral underpinnings; ethics can therefore be conceptualized as morality in action. This is distinct from laws, which are specific rules that have attendant consequences and penalties when they are violated. A particular act may be ethical while being illegal (a woman driving alone in Saudi Arabia) or legal while being unethical (racist speech in the United States).

Professionalism, in contrast, focuses on the role of the physician as professional, and expectations that are inherent in this professional role.

Professional morality may be broader and deeper than common morality, as it addresses the moral expectations for a particular group.^{19–22} Thus the American Academy of Dermatology’s (AAD) Ethics Pledge, for example, includes a broader group of commitments than would be expected of a member of the general public.²³ Indeed, biomedical ethics has been codified repeatedly, whether in Percival’s book, the AMA’s original ethics code (first published in 1847), or the AAD’s Ethics Pledge.

Ethical frameworks

Principlism

Over the past few decades, biomedical ethics, particularly in the United States, has become largely synonymous with principlism. This ethical framework, stemming largely from the seminal Belmont Report, focuses on four principles considered when evaluating an ethical conundrum (Table 9-1).²⁴ The Belmont Report outlined the principles of respect for persons (autonomy), beneficence (and nonmaleficence), and justice. These principles have been popularized and are now so enmeshed in the modern understanding of bioethics that principlism is in many areas seen as synonymous with bioethics.

Table 9-1. Principles of Bioethics

Principle	Definition
Autonomy	Patients should be treated as autonomous agents.
Beneficence	Patients should be treated for their benefit.
Nonmaleficence	Patients should not be harmed.
Justice	There should be fairness in ethical action.

Note: All principles are weighted equally.

First, the principle of autonomy focuses on the premise that individuals should be treated as unique persons, and that their individual autonomous

choices should be respected. The corollary of this approach is that those with diminished autonomy (children, prisoners, and others) should be entitled to special protection. Second, the principle of beneficence touches on an obligation by physicians to secure the well-being of their patients. In the Belmont Report, its corollary, nonmaleficence, or *not* harming the patient, was included under a single rubric. Finally, the principle of justice touches on an underlying need for fairness.

The need for a consistent ethical framework led to the expansion of principlism to the point that the four principles are frequently used as a litmus test for ethical legitimacy. Still, the challenges of this model of applied ethics may be substantial,^{25,26} and some philosophers have argued that the very model of medical ethics appropriating philosophical doctrines is flawed.¹¹

Casuistry

The casuistic method involves the extrapolation of the circumstances of one accepted or paradigmatic case to a new circumstance in order to develop a valid ethical decision (Table 9-2).^{27–30} This approach, rooted in Talmudic and ancient Christian exegesis, is frequently applied today in the field of law. Rather than relying on potentially arbitrary principles, the casuistic approach instead turns to paradigmatic cases where the ethical course of action has either already been determined or is *prima facie* clear. While this approach is predicated on the proper determination of relevant cases,³¹ its advantage is that it is rooted in an intuitive common-sense approach to ethics.

Table 9-2. Ethical Approaches

Approach	Definition
Principlism	Four principles determine ethical action.
Casistry	Prior cases determine ethical action.
Utilitarianism	Maximizing benefits determines ethical action.
Deontological	Rules dictate ethical action.
Rights theory	Respecting the actor's rights determines ethical action.
Virtue ethics	Cultivating virtues determines ethical actions.
Aspirational ethics	Obligations (at a minimum) and supererogation (ideally) determine ethical action.

Utilitarianism

Unlike principlism, predicated on the inherent value of a set of accepted principles, utilitarianism is a consequentialist approach that aims to do the greatest good for the greatest number—to maximize utility.^{32,33} One advantage of utilitarianism is that it does not require the intellectual exercise of accepting four, and only four, principles as the bedrock of ethical action. Still, a utilitarian approach that requires the physician to dispassionately create the most good (or cause the least harm) over all else necessarily creates secondary questions, including perspective (doing the most good for whom?), paternalism (who decides on what is the most good?), and possible ethical conflicts (utilitarianism embodies the idea that the end indeed justifies the means). Other concerns regarding utilitarianism include the demandingness objection (the concept that pure utilitarianism may be too demanding to be adopted on a practical level),³⁴ and the risks of unjust distribution, as doing the greatest good for the greatest number may consistently marginalize minority groups.

Deontological approaches

Deontological, or rules-based, ethical approaches are another prism through which ethical action may be viewed.^{32,33} Kant's categorical imperative aims to simplify and codify ethical action, by stating that one should never act except in such a way that they would wish the maxim driving their actions to become universal. His approach has also been outlined as the unacceptability of treating others as a means alone. This obligation-oriented approach is fundamentally different from the utilitarian approach, where the *outcomes* of the action govern its ethical legitimacy; for the Kantian, the *motives* of the action decide on its ethical grounding.

Another deontological approach is the divine command theory—the idea that while adherence to rules and obligations indeed determine the rightness of an action, the source of such obligations is not a rational actor's decision, but divine law. Thus religiously rooted ethical frameworks represent a form of deontological ethics; the rightness and morality of an action are determined by whether it was ordered by God.

Rights theory

Rights theory, the concept that the ethics of an action is determined based on their alignment with a set of human rights, is another approach to bioethics.³⁵ The idea of moral rights (what the target of action is *owed*) differs fundamentally from the idea of moral obligation (what the actor is *obligated* to do), although in practice ethical actions often align. Since rights represent an entitlement, they may be attractive when trying to protect a group of patients. Yet since rights theory does not address the rights of the community at large, it leads to possible challenges when attempting to formulate a general framework for biomedical ethics that may be applied universally.

Virtue ethics

Unlike utilitarian and deontological approaches, virtue ethics focuses not on the obligations of an actor, but on the underlying virtues that are cultivated by individual actions.^{21,36–45} If an action cultivates virtuous traits, then it is ethical. Like Kant, an Aristotelian virtue ethics approach determines an action's value based on the *motivations* of the actor, not their actions. A virtue-ethics approach embodies the idea that character is destiny; obligation-oriented approaches that set out a minimum list of rules and

obligations do not, to the virtue ethicist, lead to better behavior. Virtuous judgments, therefore, are seen as the basis of ethical action.

Virtue ethics has been used to delineate a set of ideal virtues—the professional responsibility model—for the physician leader as well.²⁰ Such virtues include self-effacement, self-sacrifice, compassion, and integrity. Like principlism, virtue ethics may be criticized for its seemingly arbitrary selection of virtues, a shortcoming that becomes particularly apparent when disparate virtues are functionally competing.

Aspirational ethics

Aspirational ethics is a synthesis of obligation- and virtue-based approaches.^{34,46–48} Like obligation ethics, it accepts that there is a set of obligations that may be codified to set a *minimum* level of acceptable behavior. But like virtue ethics, aspirational ethics focuses on cultivating a set of actions that motivate the actor, essentially moving from the normative (what is absolutely required) to the supererogative (what would be ideal).^{34,46,47} By combining the strengths of principlism, utilitarianism, and deontological approaches (setting an ethical floor) with the ideals of virtue ethics (aiming for an ethical ceiling) and aspirational ethics both guarantees basic safeties and protections while concomitantly promoting growth and excellence.

Common issues facing the dermatologic surgeon

Patient privacy and autonomy

There is a rich literature on patient autonomy. Various manuscripts have addressed the treatment of the impaired patient, the minor patient, and the prisoner.^{49–57} Ethically, the chief challenges associated with privacy and autonomy are when the ethical mandate to maintain privacy conflicts with others.

Regardless of the ethical paradigm used, maintaining patient privacy is an absolute ethical requirement for dermatologists. Pragmatically, if patients cannot rely on the privacy of their consultations, the fundamental physician–patient relationship may be undermined.^{58–61}

Duty and honesty

The issue of *duty* is important when considering ethical situations;^{18,36,62,63} most clinicians see themselves as obligated exclusively to the patient, and perceive that they have a fiduciary duty to their patient alone. In this context, an ethical choice may be interpreted as acceding to the patient's request.

A physician's duty, however, is not only to the patient; it is also to the profession, the healthcare system at large, and to the insurer with whom the clinician has a contractual relationship. From a principlist approach, this also touches on the principle of justice. Others have suggested that truth-telling itself is a principle, rather than a virtue.⁶⁴ Dermatologic surgeons should never take any steps that could erode patients' trust in physicians overall, as our standing—and thus our ability to have patients share openly and honestly—is based on perceived honesty and integrity.^{65–71}

Rationing

Appropriate use criteria (AUC) were developed jointly by the AAD, American Society for Dermatologic Surgery, American College of Mohs Surgery, and the American Society for Mohs Surgery, and have been widely popularized and adopted.^{72,73}

The ethics of this rationing behavior have not been exhaustively explored.^{74,75} Though it is tempting to accept AUC as de facto *ethical* guidelines, these criteria were developed with an eye to mitigating the risk of reimbursement restrictions through self-regulation. As one of the most costly treatments in dermatology, Mohs surgery has undergone significant scrutiny, and its cost effectiveness has been the subject of debate.^{76–80}

This touches on the issue of conflict of interest; it could also be argued, however, that there is no true *conflict* here at all. For the patient, Mohs surgery provides the greatest chance of tumor removal coupled with the smallest scar; for the physician, it provides the greatest reimbursement and the satisfaction of knowing that the patient's best interests were served. What duty does the physician have to the insurer beyond a contractual relationship? While this could be framed as a justice issue, would its outcome be different if the patient were insured through a state-funded plan or an expensive private insurer? On a pragmatic level, the patient's insurer may have a policy in place regarding reimbursement for Mohs in low-risk locations, though

patient preferences remain an important consideration when determining treatment options.

Cosmetic dermatologic surgery

Dermatologic surgeons perform a significant proportion of all cosmetic procedures worldwide.⁸¹ Patients may present for cosmetic intervention with a variety of concerns, and a reluctance to rely on paternalism, coupled with the economic realities of an out-of-pocket reimbursement schedule, has led to the embrace of a patient-as-client phenomenon. Yet the ethical obligations of the physician remain unchanged, regardless of whether the patient is presenting for cosmetic or medical treatment.

Body dysmorphic disorder is a common condition, and identifying such patients is an important challenge for the cosmetic dermatologist, not least because the patient is likely to be dissatisfied after *any* intervention.^{82–98} Ethically, performing a procedure on a patient with body dysmorphic disorder, or even a patient with clearly unrealistic expectations, is problematic. From a principlist standpoint, this would violate the principle of nonmaleficence and from a Kantian perspective, the physician's motivation is likely not the patient's best interests.

Clinical research

As with other situations resulting from solicitations, it is important to consider the *motivations* for performing clinical research. This Kantian approach is helpful in evaluating the ethical merits of performing this type of work, and the appropriate interactions that should take place both with the research sponsor and the clinical trial participants.

Clinical research is a burgeoning area in medicine overall, and indeed a necessary component in the development of both novel and generic medications.^{99–102} While it should not be pursued solely as a potential profit center, fair reimbursement for clinical research work is reasonable and indeed necessary.

Industry funding

Despite significant efforts to protect medical education from the impact of industry funding and potential bias, a significant proportion of continuing

medical education (CME) material is industry sponsored, either directly or indirectly.^{103–108}

Industry funding in dermatology is pervasive, as demonstrated by a recent manuscript highlighting the range of payments from pharmaceutical companies to dermatologists.¹⁰⁹ Accepting payments from industry is not ethically fraught per se, though significant evidence has demonstrated that even accepting drug samples has an impact on prescribing patterns.^{110,111}

CONCLUSIONS

Dermatologic surgeons face ethical challenges on a daily basis. A basic appreciation of the various approaches to ethical decision making is helpful for the practicing clinician as well as the academic dermatologic surgeon. Ultimately, most ethical guidelines set only a floor for ethical action, limiting frankly unethical actions. Aspiring to a higher level of patient-centered surgical care aids dermatologic surgeon and patient alike.

CHAPTER 10 Billing and Financial Considerations in Dermatologic Surgery

Alexander Miller
Ann F. Haas

SUMMARY

- The goal of complete and accurate coding is to clearly define to a payer what was performed during a given patient care interaction.

- Each procedural charge submitted to a payer must be correlated with a valid diagnostic code.

Beginner Pearls

- Determine the excision code size by adding the maximum lesion diameter to that of the summed narrowest bilateral excision margins.
- If a patient evaluation leads to a 90-day global procedure done on the same day, then the evaluation and management service is separately billable with modifier .57 appended.

Expert Pearls

- Immunohistochemical stain coding is defined as per specimen, and not per block of tissue.
- Redundant tissue removal (standing cones or dog ears) does not elevate an otherwise linear closure procedure to the level of a flap, though it may turn an otherwise intermediate into a complex linear repair.

- When a defect or a portion of a defect is repaired with a Burow's graft generated from a linear excision and closure adjoining the defect, only the skin graft procedure is billable, as the graft code includes the excision and direct closure of the donor defect. Mohs surgery is still billable separately, though it may be subject to the multiple procedure reduction rule.

Don't Forget!

- When more than one repair of the same type (simple, intermediate, or complex) is done within one anatomical area, sum the lengths of the repairs and bill for one closure, as directed by the site and sum of the of the repair lengths. If repairs of the same type are done in different anatomical code group areas, then bill each one individually.
- A Z-plasty generated from the edge of a flap to promote the flap's mobility does not constitute an additional separate flap.

Pitfalls and Cautions

- Avoid using “unspecified” (NOS—Not Otherwise Specified) diagnostic codes, highlighted in yellow in the ICD-10 manual, as this indicates that the medical record lacked sufficient information for a more precise code selection. Some insurers may deny claims with “unspecified” codes.

- Excisions of epidermal inclusion and pilar cysts that extend into the subcutaneous space should be coded with the integumentary excision codes, as these entities are of skin, and not subcutaneous, origin.

Patient Education Points

- It is worth explaining to patients that physicians will bill insurance companies as a *courtesy* to them, but that ultimately it is the patient's responsibility to cover the cost of any procedures performed.
- Explaining that the surgeon is bound by the terms of a contract with the insurer helps the patient understand that the surgeon is indeed their ally.

CHAPTER 10 Billing and Financial Considerations in Dermatologic Surgery

INTRODUCTION

Surgical dermatology encompasses a variety of both therapeutic and cosmetic procedures. An appreciation of the techniques needed to optimally document the patient record and convey what was done into the billing system and, ultimately, to the payer, is of vital importance. Crucial to success in this arena is an understanding of both diagnostic and procedural billing definitions and parameters.

Although electronic health records and practice management programs may prompt diagnostic and procedure code selections, it is essential to be familiar with optimal diagnostic and procedural code definitions and correlations, as ultimately correct coding is the physician's responsibility. To that end, minimal essential coding sources are the latest ICD-10-CM diagnostic coding manual and the Current Procedural Terminology (CPT®) manual, both of which are available from the American Medical Association (AMA) and from other sources.

The billing process should consider whether a given entity and its treatment are considered medically necessary/covered services or not

medically necessary/not covered. Medicare, for example, excludes coverage for procedures not aimed at improving a patient’s health or function.

The goal of complete and accurate coding is to clearly define to a payer what was performed during a given patient care interaction. As this information is typically transmitted electronically via diagnostic, procedural, and modifier codes, it is essential to proper claim adjudication that the codes precisely define what was done, and that the patient record supports the transmitted billing data.

ESSENTIALS OF CODING

ICD-10-CM: diagnostic coding

Each procedural charge submitted to a payer must be correlated with a valid diagnostic code. The chart record must specify data facilitating precise code selection. This includes a specific diagnosis or tumor type, including anatomic location and laterality. The billing system and/or biller should be able to successfully select an appropriate diagnostic code based upon the submitted information. Similarly, insurers, upon chart audit, should be able to readily extract the same information from the patient record.

ICD-10 code selection should be performed to the highest level of specificity available within each code set. If a code listed in the ICD-10 manual is accompanied by an adjacent red box, then the more detailed codes below this listing should be selected, as insurers are unlikely to pay for an inadequately specific diagnosis code. Essential documentation and code selection steps for ICD-10 coding are summarized in [Table 10-1](#). It is important to note that common (e.g., basal cell carcinoma, squamous cell carcinoma, benign nevi) and some rare tumors (e.g., Merkel cell carcinoma) have dedicated diagnostic codes, while many others do not. If the tumor diagnosis is known, then select a tumor-specific code. If a specific code is not available, then select an “other specified malignant neoplasm” site-specific code. [Table 10-2](#) provides a listing of common skin neoplasms and their ICD-10 code series.

Table 10-1. Essential ICD-10 Coding Parameters

- Tumor type
 - Specific diagnosis known
 - Use tumor-specific code if available
 - Specific code not available: use “other specified malignant neoplasm” code
 - Uncertain diagnosis: neoplasm of uncertain behavior: D48.5 (skin); D37.01 (lip mucosa)
 - Tumor location—always specify
 - Laterality—left or right
-

Table 10-2. ICD-10-CM Codes for Common Cutaneous Neoplasms

Tumor	ICD-10 Code Series
Actinic keratosis	L57.0
Basal cell carcinoma	C44 series
Benign neoplasm, lip mucosa	D10.0
Benign neoplasm, penis	D29.0
Benign neoplasm, scrotum	D29.4
Benign neoplasm, skin	D23 series
Benign neoplasm, vulva	D28.0
Cherry angioma	I78.8
Cyst, eyelid	H02.82 series
Cysts, other, follicular, of skin	L72.8
Epidermal inclusion cyst	L72.0
Hemangioma	D18.01
Hypertrophic scar	L91.0
Lipoma	D17 series
Malignant melanoma	C43 series
Malignant neoplasm, lip vermilion	C00. series
Malignant neoplasm, type known	C44 series
Mass/swelling	R22 series
Melanoma in situ	D03 series
Merkel cell carcinoma	C4A series
Neoplasm, uncertain behavior	D48.5
Nevus, melanocytic	D22 series
Pilar cyst	L72.11
Port wine stain	Q82.5
Pyogenic granuloma	L98.0
Sebaceous cyst (steatocystoma)	L72.3
Seborrheic keratosis	L82.1
Seborrheic keratosis, inflamed	L82.0
Spider angioma	I78.1
Squamous cell carcinoma	C44 series

Squamous cell carcinoma in situ, penis	D07.4
Squamous cell carcinoma in situ	D04 series
Strawberry angioma	Q82.5
Trichodermal (proliferating pilar) cyst	L72.12
Venous lake	I78.8

When a patient evaluation consists substantially of monitoring for new or recurrent tumor appearance, one may justify the visit with an ICD-10 diagnosis of personal or family skin cancer history, listed in [Table 10-3](#).

Table 10-3. Personal or Family History of Malignant Neoplasm ICD-10 Codes

Z85.42	Personal history of malignant neoplasm of other female genital organs
Z85.49	Personal history of malignant neoplasm of other male genital organs
Z85.818	Personal history of malignant neoplasm of other sites of lip, oral cavity
Z85.820	Personal history of malignant melanoma of skin
Z85.821	Personal history of Merkel cell carcinoma
Z85.828	Personal history of other malignant neoplasm of skin (BCC, SCC, others)
Z85.831	Personal history of malignant neoplasm of soft tissue
Z80.8	Family history of malignant neoplasm of other organs or systems (may be used for specifying family history of melanoma)

Coding Hint: Avoid using “unspecified” (NOS—Not Otherwise Specified) diagnostic codes, highlighted in yellow in the ICD-10 manual, as this indicates that the medical record lacked sufficient information for a more

precise code selection. Some insurers may deny claims with “unspecified” codes.

Current Procedural Terminology: procedural coding

The CPT® manual specifies numerical or alphanumeric codes for medical services. These codes are linked to appropriate ICD-10-CM diagnostic codes for the purposes of transactional record-keeping and billing.

Essential to the process is an understanding of the CPT® manual, which contains several sets of codes. Category I numerical codes represent the bulk of the manual, and are used for specifying most physician services. Category II codes, consisting of four numbers followed by the letter F, are tracking/performance measurement codes, and may be used for data collection. They are typically not necessary for billing. These codes are distinct from the “quality” reporting measures that may be reported for the purpose of avoiding Medicare payment reductions. Category III codes are temporary codes defining emerging technology, services, or procedures. They are sometimes reimbursable, are also used for tracking utilization of the item that they specify, and should be used whenever a service specified by those codes is provided. They are identified by four numbers followed by the letter T. Dermatology is served by several Category III codes ([Table 10-4](#)). These codes may eventually be changed to Category I codes if their utilization/reporting were to support such a need. Appendix A of the CPT® also lists modifier codes, which will be addressed further in this chapter.

Table 10-4. Dermatology-Related Category III CPT Codes

0394T	High-dose-rate electronic brachytherapy, skin surface application, per fraction, includes basic dosimetry, when performed
0400T	Multispectral digital skin lesion analysis of clinically atypical cutaneous pigmented lesions for detection of melanomas and high-risk melanocytic atypia; one to five lesions
0401T	Multispectral digital skin lesion analysis, six or more lesions

COMMON DERMATOLOGIC SURGERY CODES

Most dermatology-related CPT codes appear in the Integumentary System section of the codebook (codes 10030–19499). All of these procedure codes include local anesthesia in their definitions.

Biopsy: 11100 and 11101

Definition: Removal or sampling skin tissue or mucous membrane for histopathologic examination. The depth of the biopsy may extend partially into the skin or through the skin, encompassing underlying subcutaneous or muscle tissue. Suturing may or may not be necessary. While the code definition specifies skin or mucous membrane biopsy, there are several other, site-specific biopsy codes that may be utilized. Since coding should be performed to the most exacting specificity, the site-specific codes ([Table 10-5](#)) should be utilized when appropriate. For skin biopsies, the same code is applied, regardless of the depth and the width of the biopsy.

Table 10-5. Site-Specific Biopsy Codes

CPT Code	Definition
11100	Biopsy of skin, subcutaneous tissue, and/or mucous membrane (including simple closure)
11101	Each separate/additional lesion
11755	Biopsy of nail unit (plate, bed, matrix, hyponychium, proximal, and lateral nail folds)
30100	Biopsy, intranasal
40490	Biopsy of lip mucosa
40808	Biopsy, vestibule of mouth
41100	Biopsy of tongue; anterior two-thirds
41105	Biopsy of tongue; posterior one-third
41108	Biopsy of floor of mouth
54100	Biopsy of penis
56605	Biopsy of vulva or perineum; 1 lesion
56606	Biopsy of vulva or perineum, each separate additional lesion
67810	Incisional biopsy of eyelid skin including lid margin
69100	Biopsy external ear

Coding Hint: CPT® code 67810 is to be used only when lid margin, extending across the lash line to the conjunctival mucosa, is biopsied. Biopsy of the skin of the eyelid is to be coded with 11100 or 11101.

Shaving of epidermal or dermal lesions: 11300–11313.

Definition: Removal of epidermal or dermal lesions via a transverse, horizontal incision. Proper codes are determined by the maximum *diameter* of the removed lesion. Depth of lesion removal does not penetrate into the subcutaneous fat. No suturing is required for this coding level. Code selection requires specifying the location and diameter of the lesion. Typical

use of a shave code would be to specify tangential removal of a benign nevus, a fibrous papule, a cherry angioma, or a seborrheic keratosis.

Coding Hint: If the depth of lesion removal extends beyond the dermis, into the subcutaneous space, then a shave removal code is not appropriate. Select a biopsy or excision code.

Excisions, benign and malignant: 11400–11646

Definition: Full-thickness (through the dermis) lesion removal, including margins, and simple closure. The CPT does not require that the closure of a defect be performed in order to qualify for an excision code. The appropriate code is determined by the lesion location and the maximum diameter of the lesion including the narrowest margin required bilaterally. The lesion and margin measurements must be performed prior to the actual excision, as following an excision the tissue tends to rebound away from the excision center, thereby enlarging any diameter measurement (Fig. 10-1). The integumentary excision codes include local anesthesia and a simple (nonlayered) repair in their definition and valuation. Whenever an intermediate or complex repair is necessary, it is coded in addition to the appropriate excision code.

Figure 10-1. When billing for an excision, add the largest diameter of the defect as well as any necessary margins.

Coding Hint: Determine the proper code by adding the maximum lesion diameter to that of the summed narrowest bilateral excision margins prior to excision.

Several localized special excisional procedures are characterized by their own descriptive excision codes, listed in [Table 10-6](#). Note that the excisions in [Table 10-6](#) include closure, even when not specified, so that separate intermediate or complex repair should not be coded in addition to the excision code.

Table 10-6. Special Excision Procedure Codes

Nail Unit	
11750	Excision of nail and nail matrix, partial or complete, for permanent removal
Nose	
30120	Excision or surgical planning of skin of nose for rhinophyma
Lips	
40500	Vermilionectomy (lip shave), with mucosal advancement
40510	Excision, transverse wedge excision with primary closure
40520	V-excision with primary direct linear closure
40530	Resection of lip, more than one-fourth, without reconstruction
Mouth Vestibule	
40810	Excision of lesions of mucosa and submucosa; without repair
40812	With simple repair
40814	With complex repair
40816	Complex, with excision of underlying muscle
Tongue	
41110	Excision of lesion of tongue without closure
41112	Excision of lesion of tongue with closure; anterior two-thirds
Ear	
69110	Excision external ear; partial, simple repair

There are some similarities and some clear distinctions between the biopsy, shave, and excision code definitions. [Table 10-7](#) characterizes the commonalities as well as the distinctions between these three code families.

Table 10-7. Biopsy versus Shave versus Excision

Procedure	CPT® Code	Select Code by Location?	Select Code by Diameter?	Depth	Code Includes	Code Distinguishing Features	Submitted for Pathology?
Biopsy	11100, 11101	No	No	Any: not specified	Simple closure	Biopsy of skin, mucous membrane or subcutaneous tissue	Yes
Shave	11300–11313	Yes	Yes: lesion diameter	Epidermis or dermis only	Chemical or electric cauterization	No suture closure	Usually
Excision	11400–11646	Yes	Yes: greatest lesion diameter + margin	Full thickness, through dermis	Excision with margins; simple closure	Report intermediate or complex repair separately; closure not required for use of code	Yes

Soft tissue excision (musculoskeletal section of CPT®)

Codes specifically dedicated to the excision of subcutaneous and subfascial tumors are grouped in multiple locations within the musculoskeletal section of the CPT®, starting with code 21011 for an excision of a subcutaneous tumor less than 2 cm in diameter on the face or scalp, and ending with 28041 and 28045 for subfascial tumor excisions on the foot or toe.

These specialized codes are appropriate for the resection of typically benign tumors of subcutaneous or subfascial origin, such as lipomas. Code selection is based upon tumor location on the body, whether it is subcutaneous or subfascial in origin, and upon its maximum diameter being either above or below a limit specified by an individual code. The medical record should substantiate the depth of excision and the type of tumor excised. Radical resection codes, such as 21015 for face or scalp, are major procedures reserved for aggressive tumor resections, such as deep tissue sarcomas.

Coding Hint: Excisions of epidermal inclusion and pilar cysts that extend into the subcutaneous space should be coded with the integumentary excision codes, as these entities are of skin, and not subcutaneous, origin.

Repairs

All repair codes include local anesthesia and wound closure with sutures, staples, or tissue adhesives. Closure with adhesive strips only does not merit

a repair code, and is included in an evaluation and management code. Code selection is based upon location and measured length of the repair.

Coding Hint: When more than one repair of the same type (simple, intermediate, or complex) is done within one anatomical area, sum the lengths of the repairs and bill for one closure, as directed by the site and sum of the repair lengths. If the repairs of the same type are done in different anatomical code group areas, then bill each one individually.

Simple repair: 12001–12021

Definition: Single-layer closure for a usually superficial wound. Biopsy and excision codes include a simple repair. However, Mohs surgical excisions do not. Consequently, other than for the repair of traumatic skin injuries, one is most likely to use a simple repair code in conjunction with a Mohs surgical defect repair.

Intermediate repair: 12031–12057

Definition: Specifies “wounds that, in addition to simple repair, require layered closure of one or more deeper layers of subcutaneous tissue and (nonmuscle) fascia, in addition to the skin (epidermal and dermal) closure.” Typically, the medical record would include a justification for an intermediate repair, such as reducing closure line tension, obliterating dead space, or providing stability to the wound. Rarely, an intermediate repair may be justified when extensive removal of particulate matter is done prior to a single-layer closure.

Complex repair: 13100–13153

Definition: These repairs are more involved than a layered closure, and include any of the following: scar revision, debridement, extensive undermining, dog-ear correction, stents, or retention suture placement. The most common dermatologic surgical justification for complex repair coding is extensive (broad) undermining, though this definition is not specifically addressed in the CPT® or other official publications. The breadth of

undermining required to qualify as “extensive” will vary by anatomical site as, for example, what one may consider to be broad undermining on the nose tip would not necessarily be the same as that on a cheek. It is clear, however, that undermining done minimally beyond the wound edges in order to optimize apposition is not extensive undermining. Consequently, undermining alone does not justify a complex repair code. It has to be extensive (broad), and documented as such. Also, document why extensive undermining was performed, such as due to tension across the wound or to reduce distortion. The repair of Burow’s triangles (standing cones or dog-ears) is included in this code.

Coding Hint: The length of a repair of standing cones (Burows triangles, “dog ears”) is contiguous with the principal repair itself, and should be included in the final repair length measurement.

Clinical Scenario: Your patient returns with a wound dehiscence, which you clean and repair. How do you code for the procedure? If the procedure is, in your judgment (and documented), extensive or complicated, use CPT® 13160, Secondary closure of surgical wound or dehiscence, extensive or complicated. If it requires a simple closure, use CPT® 12020, and if packing was included, then use 12021.

Destruction: 17000–17004, 17100–17111, 17260–17286

The destruction code set is principally stratified into two major sections, one dedicated to the destruction of malignant lesions, and the other for benign or premalignant entities. Both categories include destructions by “any method,” examples being laser surgery, electrosurgery, cryosurgery, chemosurgery, and surgical curettage. Specialized destruction categories are dedicated to vascular proliferative lesions (17106–17108) and to the chemical cauterization of granulation tissue (17250). Typically, no tissue is submitted for histopathology prior to the destruction of a benign or premalignant lesion, but there is nothing in the codes prohibiting histopathologic examination, if that were medically necessary. The CPT also offers some special, site-specific destruction codes ([Table 10-8](#)).

Table 10-8. Site-Specific CPT® Destruction Codes

■ 40820	Vestibule of mouth, by physical methods
■ 46900	Anus, simple; chemical
■ 46910	Simple, electrodesiccation
■ 46916	Simple, cryosurgery
■ 46917	Simple, laser surgery
■ 46922	Surgical excision
■ 46924	Anus, extensive ^a (laser, electrosurgery, cryosurgery, chemosurgery)
■ 54050	Penis, simple; chemical
■ 54055	Simple, electrodesiccation
■ 54056	Simple, cryosurgery
■ 54057	Simple, laser surgery
■ 54060	Surgical excision
■ 54065	Penis, extensive ^a (laser, electrosurgery, cryosurgery, chemosurgery)
■ 56501	Vulva, simple (laser, electrosurgery, cryosurgery, chemosurgery)
■ 56515	Vulva, extensive ^a (laser, electrosurgery, cryosurgery, chemosurgery)

^a“Extensive” is not specifically defined in the CPT.

Malignant destruction: 17260–17286

Coding is specified by lesion location and diameter, performed either prior to the destruction, after curettage, or after electrodesiccation or chemical hemostasis. As curettage may reveal substantial subclinical extension of a tumor, it is best to measure after curettage, as that will yield the most accurate indication of a lesion’s diameter. Electrodesiccation can shrink the apparent diameter, so it is prudent to avoid measurements following electrodesiccation, if curettage is first done. It is helpful to identify in the medical record both the lesion diameter and at which point it was measured (i.e., following curettage). The depth of curettage is not required to be recorded, but can be useful for evaluating the risk of tumor recurrence.

Coding Hint: If one of the first samples is presumed malignant tissue for histopathologic evaluation immediately prior to its destruction, then no separate biopsy or shave removal charge is allowed. The removal of the lesion in the setting of its destruction is included in the destruction code set.

Mohs micrographic surgery: 17311–17315

Definition: Removal of skin cancer with histologic examination of 100% of surgical margins. A qualifying requirement is that the physician functions as both a surgeon (excises the cancer) and pathologist (interprets the Mohs histology slides). Mohs surgical codes are stratified by a primary (17311, 17313) location-based code for the first stage of excision and a corresponding add-on code (17312, 17314, respectively) for each additional stage. Each of the stages includes processing tissue into up to five blocks. If more than five blocks are required for a stage, then 17315 is coded for each additional block per stage beyond five ([Table 10-9](#)). A block is defined as an individual tissue piece or pieces embedded in a mounting medium on a tissue plate. It is the number of separate tissue plates needed to process a tissue specimen in a given stage that determines the number of blocks, and not the number of pieces of tissue on a plate. Staining with hematoxylin and eosin or toluidine blue, or both, is included in the Mohs definition. Other, special histochemical stains may be coded with 88314.59, reported once per block. Immunohistochemical stains, such as melan-A, are specified with 88342.59 for a single antibody stain per specimen, and 88341.59 for each additional, distinct antibody stain, per specimen (not per block).

Table 10-9. Mohs Surgery Codes

Each Mohs stage includes:

- Staining with a “routine” stain: hematoxylin and eosin, and/or toluidine blue
- Processing of tissue into up to five tissue blocks

17311	First stage: head, neck, hands, feet, genitalia; any location involving muscle, cartilage, bone, tendon, major nerves, or vessels
17312	Each additional stage after the first stage
17313	First stage: trunk, arms, legs
17314	Each additional stage after the first stage
17315	Each additional tissue block over five blocks per stage

Coding Hint: Immunohistochemical stain coding is defined as per specimen, and not per block of tissue. A specimen is a distinct piece of tissue excised in a Mohs stage. If one specimen is sectioned into multiple pieces, each processed on a separate block, one would charge for one unit of 88342 histochemical staining. However, if a Mohs stage required an excision of two separate, noncontiguous tissue specimens from two separate portions of the defect margin, and each of these was stained immunohistochemically, then two units of 88342 would be billed.

In 2013, Medicare issued a Medicare Learning Network (MLN) Matters article (<https://www.cms.gov/Outreach-and-Education/Medicare-Learning-Network-MLN/MLNMattersArticles/Downloads/SE1318.pdf>) defining qualification and documentation criteria for Mohs surgery. These criteria have been widely adopted by individual Medicare Administrative Contractors, the entities charged with adjudicating claims. As the Medicare patient population continues to expand, it is wise to incorporate the MLN Mohs article’s requirements into charting. The salient features are summarized in [Table 10-10](#).

Table 10-10. Mohs Surgical Documentation, Based upon MLN 2013 “Guidance to Reduce Mohs Surgery Reimbursement Issues”

Documentation Supporting the Choice of Mohs Surgery

- "Complexity" of a lesion: poorly defined borders (indistinct clinical margins), deep invasion, recurrence, prior irradiation
- Lesion size or location (on anatomically or functionally critical site)
- Maximum conservation of healthy tissue

Qualifications and Limitations of Coverage

- Mohs surgeon must be a physician: MD or DO
- Physician must be skilled and trained in Mohs surgery and pathology interpretation
- Physician performs both the surgery and the specimen interpretation (this must be documented in the operative report)

Operative Documentation

- Location, number and size of the Mohs treated lesion(s)
- Number of stages performed
- Number of specimens per stage

Histology Documentation

- First stage:
 - Depth of invasion
 - Pathological pattern of the tumor
 - Cell morphology
 - Perineural invasion or scar tissue, if present
- Subsequent stages:
 - If tumor characteristics are unchanged, note this only
 - If tumor characteristics are different, describe the differences

Mohs surgery special circumstances

Mohs surgery continued on a subsequent day.

The MLN article directs one to start with a first stage code when a Mohs surgery is continued on a subsequent day. Example: Four stages, nose, on day one: 17311, 17312 × 3; two stages on day two: 17311, 17312.

Biopsy done to confirm the presence and type of tumor on the day of Mohs surgery, when no biopsy was previously performed.

One would do a diagnostic biopsy and a diagnostic frozen section tissue processing and reading. The proper billing would be: 11100.59 for the biopsy and 88331.59 for the frozen section pathology. The .59 modifier indicates that both the biopsy and the frozen section are separate, distinct services that should not be bundled with the Mohs surgery adjudication. The Mohs surgery would be billed without a modifier.

Two separate Mohs sites/surgeries on one patient, one day.

First site: code routinely for Mohs.

Second site: append .59 modifier to all codes. (Medicare contractors may require appending .76 modifier (“Repeat procedure or service by the same physician or other qualified health care professional”), instead.

Biopsy of a totally distinct lesion done on the same day as Mohs surgery.

Bill Mohs surgery routinely.

Bill biopsy as 11100.59 or 11100.76 (if Medicare patient).

Decision to do Mohs surgery is made on the same day as the Mohs surgery.

If a patient evaluation led to a Mohs surgery recommendation, and the surgery was done on the same day, one may bill for an appropriate level of evaluation and management (E/M) service in addition to the Mohs surgery. The E/M would be billed with an appended .57 modifier, indicating that that an E/M evaluation that led to a decision to perform Mohs surgery was done on the same day as a major surgical procedure.

Adjacent tissue transfer or rearrangement (flaps): 14000–14302

Definition: Includes excision of a lesion as well as a repair of the defect by adjacent tissue transfer or rearrangement, with one exception: Mohs surgery-generated excisions are separately billable from any repair code, including flap repairs. The CPT® specifies that the extent of undermining to generate tissue motion does not make the procedure a flap. For example, broad undermining of a cheek to facilitate “advancing” it to close a nasofacial sulcus or preauricular defect linearly does not constitute a flap procedure. Proper flap codes are determined by the location of the defect and by the measured square centimeters of the primary defect plus that of the secondary

defect created by the raised (detached) portion of the flap. This sum constitutes the “defect” size. The CPT® provides code selection based upon lesion location and defect surface areas of 10 cm² or less, 10.1 to 30.0 cm², 30.1 to 60.0 cm², any area (14301), and each additional 30.0 cm² beyond 60.0, any area (14302).

Coding Hint: Redundant tissue removal (standing cones, Burows triangles, “dog ears”) does not elevate an otherwise linear closure procedure to the level of a flap. (CPT Assistant, April 2014, page 10).

There are flaps (CPT® 15570–15738) outside of the adjacent tissue rearrangement section that are used in dermatologic surgery (Table 10-11). One should avoid using code 15740: *Flap; island pedicle requiring identification and dissection of an anatomically named axial vessel* unless the strict criterion for its use (identifying and dissecting out a named vessel) is met. Just because a named vessel may be identified and contained in the body of a V-Y flap (but not dissected out) does not qualify a repair as an island pedicle flap.

Table 10-11. Special Flap Codes

15570	Formation of direct or tubed pedicle, with or without transfer; trunk ^a
15572	Scalp, arms, or legs
15574	Forehead, cheeks, chin, mouth, neck axillae, genitalia, hands, or feet
15576	Eyelids, nose, ears, lips, or intraoral
15600	Delay of flap or sectioning of flap (division and inset); at trunk
15610	At scalp, arms, or legs
15620	At forehead, cheeks, chin, neck, axillae, genitalia, hands, or feet
15630	At eyelids, nose, ears, lips
15650	Transfer, intermediate, of any pedicle flap, any location ("walking tube")
15731	Forehead flap with preservation of vascular pedicle (paramedian forehead flap)
40525	Full thickness lip reconstruction with local flap (Estlander or fan)
40527	Full thickness lip reconstruction with cross lip flap (Abbe–Estlander)

^aThe specified location is that of the recipient defect site (not the donor area).

Coding Hint: A bilateral advancement flap constitutes one flap with two sections, just as a bilobed transposition flap is one flap with two lobe components. A Z-plasty generated from the edge of a flap to promote the flap's mobility does not constitute an additional separate flap. In the above cases, one would bill based upon the sum of the measured surface areas of the excision defect plus that of all of the raised flap components, including any Z-plasty.

Skin Replacement Surgery (Grafts): 15002–15278

This section has steadily expanded as technology has facilitated the development of skin substitutes. Coding is determined by the type of graft utilized, the location onto which it is placed, and the square centimeter surface area of the defect covered by the graft. Full-thickness skin graft codes (15200–15261) include excision of the donor skin and direct closure of the donor site. A complicated repair of a surgical defect may require a combination of a flap repair as well as a skin graft. In such cases, both the flap and the graft are separately billable.

Coding Hint: When a defect or a portion of a defect is repaired with a “kite graft” or a Burows graft generated from a linear excision and closure adjoining the defect, only the skin graft procedure is billable, as the graft code includes the excision and direct closure of the donor defect.

GENERAL CONSIDERATIONS

Global surgical periods

Each surgical CPT code is presently assigned a global surgical period, which indicates a time of 0, 10, or 90 days postprocedure during which routine office visits related to the procedure are not billable, as payment for such is included in the surgery valuation. Routine visits include wound checks, patient counseling, bandage changes, and suture removal (Table 10-12). Any necessary services provided following a 0-day global procedure are billable. Ten-day global periods include the day of the procedure plus 10 days starting on the day after the procedure. Ninety-day global periods include the day before, the day of, and 90 days starting the day after a surgery. Common dermatologic surgical codes and their global periods are listed in Table 10-13.

Table 10-12. Services Included in a Global Period

-
- Preoperative visits: day of surgery for 10-day global (minor) procedures and day before surgery for 90-day global (major) procedures

- Postoperative complications not requiring a return to the operating room (e.g., hemorrhage, infection)
- Postoperative follow-up visits
- Dressing changes, surgical site care, removal of sutures or staples
- Decision to perform a minor (10-day global) procedure made on the day of the procedure

Table 10-13. Common Dermatology-Related Global Periods and CPT Codes

0 Days	10 Days	90 Days
Biopsy (11100, 11101)	Destruction (17000–17286)	Flaps (14000–14301; 15570–15760)
Shave removal (11300–11313)	Excisions (11400–11646)	Grafts (15050–15260; 15760)
Debridement (11000–11043)	Repairs (12001–13153)	Tissue expanders
Mohs surgery (17311–17315)		Destruction of vascular Proliferative lesion (17106–17108) Dermabrasion, chemical peel.

Coding Hint: If a patient evaluation leads to a 90-day global procedure done on the same day, then the evaluation and management service is separately billable, with modifier .57 appended (see Modifiers, below).

Modifiers

Appendix A of the CPT® lists numerical modifiers that are to be appended to CPT codes to distinguish certain services or situations. Whenever an E/M encounter or a billable procedure is performed during the global period, one must append an appropriate modifier to the primary billing code to specify that the service provided is unrelated to the global period service (Table 10-14).

Table 10-14. Modifiers Commonly Used in Dermatologic Surgery

- 24: Unrelated E/M service by the same physician or other qualified health care professional during a postoperative period

- 25: Significant, separately identifiable E/M service by the same physician or other qualified health care professional on the same day of the procedure or other service
 - 57: Decision for surgery (refers to E/M service resulting in a decision to perform a 90-day global surgery the day of or day after the evaluation)
 - 58: Staged or related procedure or service by the same physician or other qualified health care professional during the postoperative period
 - 59: Distinct procedural service (append to distinguish additional procedures performed on one day)
 - 76: Repeat procedure or service by same physician or other qualified health care professional
 - 79: Unrelated procedure or service by the same physician or other qualified health care professional during the postoperative period
-

Therefore, this entails tracking of preceding services and their global periods. Modifier .24 is appended to E/M codes during the Global Period, and .79 is added to surgical/procedural codes billed during the Global Period. When a distinct, separately identifiable E/M service is provided on the day of a procedure, one appends modifier .25 to the E/M service code. The patient record should support such a claim. Routine billing of an E/M code along with every procedure will cast one as an outlier biller, and is likely to eventually result in insurance company action, such as in the form of a focused chart audit.

Occasionally, one will perform a second procedure, related to the first, during the global period. Typical scenarios include a wide excision of a melanoma within 10 days following an initial, diagnostic excision, or a division and inset of an interpolation flap during its 90-day global. Such services require appending a .58 modifier, indicating that the second procedure is a consequence of the first.

Finally, dermatologic surgeons commonly perform more than one procedure, such as multiple malignant neoplasm destructions, or actinic keratoses destructions along with unrelated lesion biopsies or destructions, during one patient encounter. Insurers must distinguish that the procedures done were separately identifiable and individually payable. Modifier .59 specifies distinct procedural services, and should be appended to secondary procedures done on one day. Medicare, however, may require a .76 modifier

when two or more procedures are done for an identical diagnosis, or when the two procedures have the same CPT® procedure code. Thus, if a Medicare claim that seems properly coded with a .59 modifier is rejected, one should consider appending a .76 modifier instead.

The choice of which code should have no modifier (primary code) and which should have a modifier is based on the National Correct Coding Initiative (NCCI), a project of the Centers for Medicare and Medicaid Services (CMS) dedicated to promoting correct coding and generating guidelines so as to avoid improper payments for Medicare outpatient services. The entity generates a Policy Manual for Medicare Services, and quarterly updated procedure-to-procedure (column 1/column 2) edits that specify whether a service paired with another is covered, and if so, which should be subject to the .59 modifier. Figure 10-2 illustrates the format of the NCCI edits and commonly used edits. The NCCI may be accessed at <http://www.cms.gov/Medicare/Coding/NationalCorrectCodInitEd/NCCI-Coding-Edits.html/>

Col 1	Col 2		19970101*		Modifier allowed? (1 = Yes)
17260	11100		19970101*		1

 Code in Col 2 gets the modifier

 Effective date of edit

Figure 10-2. NCCI edits demonstration. These tables dictate which procedure code receives a modifier for each distinct code pair.

General NCCI edits guideline:

- ✓ When a malignant destruction is done on the same encounter as a biopsy, append the .59 modifier to the biopsy code.
- ✓ When a premalignant destruction (17000) is done on the same encounter as a biopsy (11100), malignant destruction (17260–17286), benign or malignant excision (11400–11446; 11600–11646), append a .59 modifier to the biopsy, destruction, or excision codes
- ✓ Add-on codes (e.g., 11101 and 17003 do not merit a .59 modifier, as only the primary code receives the modifier)

Insurance coverage policies

Compulsively correct coding will yield no reimbursement if the procedures that are done are not considered medically necessary or are noncovered services. To that end, it is useful to know whether an insurer is likely to cover a given service. With Medicare, coverage decisions are typically reached in a transparent and reproducible fashion. CMS publishes National Coverage Determinations (NCD) that specify coverage for certain conditions. Specific to dermatology is the actinic keratosis NCD, which states that treatment of actinic keratoses is a covered service. Of greater use and impact are the Medicare Administrative Contractors' Local Coverage Determinations (LCDs), which are coverage documents issued for select conditions or procedures as a consequence of high utilization, suspected or proven fraud and abuse, due to a perception of overuse, and to standardize criteria for documentation and coverage. The LCDs specify coverage criteria, covered ICD-10 codes, pertinent CPT codes, and documentation requirements. If one fails to satisfy the LCD requirements, payment may not be forthcoming, or a refund may be requested upon audit. That should be a sufficient reason to be familiar with LCD content. The most common LCDs are for Mohs surgery and benign skin lesion treatments. The LCDs can be readily accessed from the relevant Medicare Administrative Contractor (MAC) websites.

Advanced Beneficiary Notice

The Advanced Beneficiary Notice (ABN, form CMS-R-131) is a written notice that the physician must provide to a Medicare fee-for-service patient before delivering services that are usually covered by Medicare but are not expected to be paid in a specific instance for a specific reason such as "lack of medical necessity." The ABN allows the Medicare beneficiary to be made aware that Medicare likely won't pay, and they can decide whether or not to have the procedure done. When an ABN is required, and the patient has been properly instructed and has signed the form, you can then receive payment from the patient. If Medicare feels that the ABN is invalid or if you failed to obtain one when indicated, you may be financially liable if Medicare does not pay. If payment was collected from the patient in this instance, the payment must be refunded in a timely manner. Items not covered under Medicare are listed on the CMS website at <https://www.cms.gov/Outreach-and-Education/Medicare-Learning-Network->

[MLN/MLNProducts/Downloads/Items-and-Services-Not-Covered-Under-Medicare-Booklet-ICN906765.pdf](#).

Billing Hint: If unsure as to whether a service will be covered by the patient's insurer, have the patient sign a fully filled-out ABN, available from the MAC or CMS website, prior to providing the service.

Cosmetic procedures

Report either ICD-10 code Z41.1 *Encounter for cosmetic surgery* for procedures that are strictly cosmetic in nature (such as nontherapeutic toxin injections or fillers) and then the 17999 CPT code with whatever price was quoted to the patient, or Z41.8 *Encounter for procedure for purposes other than remedying health state* when the procedure may not be considered cosmetic in all circumstances, but is in a particular case (nonirritated benign moles or skin tags), whichever is most appropriate, and then the CPT code for whatever procedure was done.

Insurer's perspectives

Health insurance will typically cover services that are both reasonable and necessary. It is incumbent upon the medical practitioner to record data supporting the decisions for care. If, upon chart audit such information is not discoverable, a claim may be denied. Each insurer may also have its own requirements for coverage or preferred claims adjudication criteria. Inappropriate denials of claims should be discoverable within one's practice. This requires a feedback and information sharing system between the billing/collections department and those actually doing the charting and generating billing: the medical care providers. This interactive interplay will facilitate discovering and correcting faulty billing patterns and/or record-keeping, and will stimulate appeals of improperly unpaid or underpaid claims.

Keep in mind that insurers utilize systems that analyze individual billing patterns, comparing them to a normal distribution curve of billings. If a practice's billing pattern rises to two standard deviations above the norm, then that practice is more likely to catch the insurer's attention, and be

audited. Examples of falling into such auditing criteria would be if all or nearly all of one's Mohs surgical cases required two or more stages for clearance, or if all linear repairs were complex repairs. If exposed to a focused audit, one would have to prove, case by case, why each patient required the complexity of care that they received.

Another subject for insurers' concern is overall cost of care. If a given practice is particularly costly to the system, then that system may want to investigate why, or may even want to drop the practice from its provider panel. It would then be up to the practice to prove why they have the expensive patient care mix, and how their practice is essential for the care of the insured patients. Insurers, and particularly Medicare Administrative Contractors, are concerned about "cloning" of chart material, whereby patient data is passed on virtually verbatim from one encounter to the next. Although cloning of individual surgical encounters is less likely, it is possible, particularly via electronic health records system facilitation, to have surgical procedure verbiage that is identical from one to another surgery, and from one patient to another. It is helpful to insert case-specific nuances into the surgical report, so that all reports do not seem identical. Finally, surgical reports should allow for extraction of pertinent care and billing data.

CONCLUSIONS

Accurate and precise coding and billing require the dermatologic surgeon to work in a logical and precise fashion. Documenting the medical necessity for every procedure is of paramount importance, and linking each procedure code to the appropriate ICD-10 diagnosis code, as well as to modifiers, if needed, will permit payers to rapidly and reliably decide on the merits of an individual surgeon's coding. Attention to detail ultimately results in fewer denials and rejections, a higher paid claims rate, a lower audit rate, and a smoother billing experience overall. Ultimately, it is the surgeon's responsibility to be familiar with the relevant coding, billing, and documentation requirements, and working as a team with the biller and collector will allow the surgeon to maintain their focus on the most important goal of all—outstanding patient care.

CHAPTER 11 Clinical Research in Dermatologic Surgery

Abigail Waldman

Molly Storer

Maryam M. Asgari

SUMMARY

- The central tenet of clinical research is answering a concrete, researchable question that addresses an uncertainty that the investigator wants to resolve.

- Clinical research is a broad, umbrella term that encompasses many types of scientific investigation including clinical trials as well as epidemiologic, behavioral, outcomes, or health services research.
- Many of the high-quality surgical techniques and improvements in clinical care enjoyed by dermatologic surgeons today result from clinical research physician–scientists.

Beginner Tips

- The foundation of any clinical research project is a clinically significant and impactful research question.
- A thorough review of the literature surrounding the clinical research hypothesis is necessary to establish the context of the work and to give it meaning.
- A systematic method for organizing and archiving the literature search is essential.

Expert Tips

- Understanding basic statistical concepts and tools can help reduce bias from potential confounding variables and improve the understanding of the application of clinical findings.
- Prior to initiating a study, a power analysis should be performed in order to determine the minimal number of data points required to reveal a significant result.
- Additional preparation for undertaking clinical research in dermatologic surgery includes refining skills in areas such as study design and biostatistics.
- The p -value is a measure of the likelihood that the result could be seen by chance. Overall, a p -value <0.05 , or less than 5%, is considered the threshold for being statistically significant; however, the lower the p -value, the more likely the result is to be true.

Don't Forget!

- Clinical trials that have one or more sites in the United States or that test a drug or device that is manufactured in the United States or its territories must be registered with ClinicalTrials.gov.
- In some cases, rigorous inclusion and exclusion criteria may select for ideal patients that fail to reflect a general population. Thus, the results of the study may not have generalizability.

Pitfalls and Cautions

- Confounding occurs when there is a factor that is related to the independent and dependent variables and thus affects the outcomes of the study.
- Bias is any error in the study design, orchestration or analysis that results in an error of inference.
- Early involvement with a statistician is recommended for those without formal epidemiologic training.
- The most interesting and novel of findings will not have any clinical impact if they are not disseminated and ultimately published.

CHAPTER 11 Clinical Research in Dermatologic Surgery

INTRODUCTION

Clinical research is defined as patient-oriented investigation conducted with human subjects aimed at advancing medical knowledge to benefit human health.¹ It is a broad, umbrella term that encompasses many types of scientific investigation including clinical trials as well as epidemiologic, behavioral, outcomes, or health services research. The central tenet of clinical research is answering a concrete, researchable question that addresses an uncertainty that the investigator wants to resolve. Dermatologic surgeons are aptly positioned to contribute significant developments in clinical research, as numerous uncertainties are encountered in daily clinical practice, and many clinical decisions are lacking a strong evidence base.

The proliferation of electronic medical records (EMRs) can allow dermatologic surgeons access to large patient databases containing key variables that enable observational clinical research and serve as a recruitment tool for interventional studies, such as clinical trials. Evidence-based clinical decision making has the potential to impact clinical care, the patient experience, and healthcare policy. The demand for minimally invasive cosmetic dermatologic procedures has also continued to trend upwards with much room for clinical research on developing and optimizing treatments.² Furthermore, recent advancements in procedural dermatology technology and techniques mandate the establishment of clinical endpoints

and continued outcome assessment, particularly patient-oriented outcomes, such as patient satisfaction and skin-related quality of life.

FORMULATING A CLINICAL RESEARCH HYPOTHESIS

The foundation of any clinical research project is a clinically significant and impactful research question. The best research questions arise from unresolved uncertainties encountered in daily practice. Clinical experience and scholarship within the field of study are both necessary for developing an informed research question. The challenge lies in transforming the clinical research question into a research hypothesis, which will guide the study protocol. The research hypothesis should be concrete and focused. For example, consider an otherwise-healthy 43-year-old male who is referred to your practice for excision of an incompletely removed nevus with moderate cytologic atypia, who inquires about the malignant potential of the nevus if left untreated. A clinical research question would be “What is the lifetime malignant potential of an untreated moderately atypical nevus in an otherwise healthy 43-year-old male?” However, answering that clinical research question would require a long-term natural history study, which would be difficult to perform and may require resources that extend beyond the scope available to the investigator. Instead the clinical research question needs to be transformed into a more well-defined, focused clinical research hypothesis question, such as “Is the 5-year risk of melanoma arising in untreated moderately atypical nevi higher than de novo melanoma in a population of patients with surgically treated moderately atypical nevi?” The later example focuses on a time period and a specific population, and is a feasible, clinically relevant question, the results of which can be extrapolated to answer the clinical research question.

HIGHLIGHTING THE KNOWLEDGE GAP: BACKGROUND AND SIGNIFICANCE

A thorough review of the literature surrounding the clinical research hypothesis is necessary to establish the context of the work and to give it

meaning. An extensive query of biomedical literature sources helps fine-tune the knowledge gap your research hypothesis aims to fill and ensures that the hypothesis or the approach to addressing it is novel. Table 11-1 outlines examples of sources of information available when using the National Library of Medicine's Gateway Web-Based System. Literature review can be performed using Pubmed for journal articles (<http://www.ncbi.nlm.nih.gov/pubmed>), Cochrane Database for systematic reviews (<http://www.cochrane.org>), and the National Library of Medicine Gateway (<https://gateway.nlm.nih.gov/gw/Cmd>). Medical librarians are also an excellent resource for guiding comprehensive literature searches.

Table 11-1. Sources of information when using the National Library of Medicine's Gateway web

Category	Collection	Data Type
Journal citations	MEDLINE/PubMed	Journal citations, 1966 to present
	OLDMEDLINE	Journal citations, 1953 to 1965
Books/serials/AVs	LOCATORplus	Catalog records for books, serials, AV materials
Consumer health	MEDLINEplus	Health information from NIH and other sources
	Health Topics	Generic and brand name drug information
	MEDLINEplus	Articles about diseases, tests, symptoms, injuries, and surgeries
	Drug Information	Information about clinical research studies
	MEDLINEplus	Directory of health organizations
	Medical Encyclopedia ClinicalTrials.gov DIRLINE	
Meeting	Meeting abstracts	Meeting abstracts on selected subjects
Other	HSRProj	Health services research projects in progress

A systematic method for organizing and archiving the literature search is essential. Services such as Endnote, Refworks, or free online resources such as Mendeley, Zotero, and F1000 Workspace can assist with organizing the initial data and can also help with the formation of a bibliography for a grant or a manuscript. Summarizing the results of a literature search in the form of a table, which includes the citation, the number of patients studied, study design, findings, and potential limitations can be very useful in honing the knowledge gap in the field, and serve as a useful tool for the research team.

DEVELOPING THE PROTOCOL

After defining the research hypothesis and highlighting the knowledge gap the work is poised to address, the next step is establishing specific components of the protocol methodology, such as the study design, the study population,

the variables of interest, and the statistical approach. A study protocol is the written plan for the clinical research study. The protocol enables organization of the research so that the project can be easily communicated to potential collaborators and funding agencies. No one approach is always the best, and each research hypothesis requires judgment about which study design, variables, and statistical methods are the most efficient in addressing the hypothesis. The following sections are aimed at improving the understanding of each of the elements of a research protocol.

Study design

There are two main classifications of study designs: one where the investigator takes a passive role in observing events (observational study) and the other where the investigator applies an intervention and examines its effects (interventional study). The randomized controlled trial is often regarded as the gold standard for establishing causality, but there are also many situations where an observations study may be a better choice (e.g., in studying rare outcomes of interest). The main limitations of observational studies are issues of bias and confounding. Confounding occurs when there is a factor that is related to the independent and dependent variables and thus affects the outcomes of the study. For instance, those who use tanning beds may participate in other high-risk activities such as drinking, smoking, or poor eating habits, all possible confounders that must be accounted for. Approaches to controlling for confounding include individual or group matching and stratification or adjustment during data analysis. Bias is any error in the study design, orchestration, or analysis that results in an error of inference. Selection, interviewer, recall, and performance bias are all common examples. An overview of study designs and considerations for when to choose the most appropriate design is presented below.

Observational studies

An observational study may be either descriptive, for example, where distributions of a disease or an exposure are described (e.g., describing trends in basal cell carcinoma incidence³), or analytic, where associations between predictors and outcomes are examined. Analytic studies are designed to test a hypothesis. Analytical observational studies can be of three

types, depending on the time sequence and sampling procedures used to collect data: case-control, cross-sectional, and cohort studies (Table 11-2).

Table 11-2. Observational Study Methods

Observational Study	Other Names	Cases	Control	Outcome	Measure
Case-control	Retrospective study	Diseased (at time of study start)	Not diseased (at time of study start), may be matched or not	% Exposed (retrospective data)	OR
Prospective cohort	Concurrent cohort, longitudinal study or prospective study	Exposed (time of study start or in the future)	Not exposed (time of study start or in the future)	Incidence rate or mortality of disease (time in the future)	RR, HR, OR, SIR, SMR
Retrospective cohort	Historical cohort study	Exposed (determined from past records)	Not exposed (determined from past records)	Incidence rate or mortality of disease (at time study has begun or outcome may be in future)	RR, HR, OR, SIR, SMR
Cross-sectional	Prevalence survey	Exposed or diseased (at time of study start)	Not exposed or not diseased (at time of study start)	Prevalence of disease	OR or relative prevalence

Case-control study. A case-control study is a retrospective observational design that observes patients who have been diagnosed with a specific disease or outcome compared to control patients, and examines the association with a certain exposure (Fig. 11-1A). Outcomes are reported as odds ratio (OR), which is defined as the odds of having a disease if you have a specific exposure. For example, a study examining patients with squamous cell carcinoma (SCC, cases) compared to those without SCC (controls) showed that those with SCC had a fourfold higher risk of having had a family history of SCC.⁴ These data were derived via questionnaires, and like most retrospective studies that utilize patient recall, are subject to recall bias as well as confounding by unmeasured variables (in this particular case, shared familial environmental exposures, such as family beach vacations)

Figure 11-1. A. Case-control study model. B. Cross-sectional study model. C. Prospective vs. retrospective cohort studies.

Cross-sectional study. A cross-sectional study examines a population in a given timeframe and provides information regarding the prevalence of disease in subjects that have a given exposure compared to the prevalence of disease in subjects that have not had the exposure (Fig. 11-1B). An example relevant to dermatologic surgery is a cross-sectional study that demonstrates an association between the location of an atypical melanocytic proliferation on the head and neck, and positive margins after excision.⁵ Because the exposure and the outcome are determined at the same time, it is not possible to determine temporal relationships between the two.

Cohort study. A cohort study follows a group of individuals with a common disease or exposure over time (Fig. 11-1C). The investigator selects a group of patients that have already been exposed to a treatment or procedure and compares an outcome of interest to an exposed group. There are two forms of cohort study: prospective and retrospective. A prospective cohort is one where the participant is exposed to the variable at a time when

the study begins or in the future, and then is followed into the future to determine outcomes. A prospective cohort study is useful for determining potential causes of a condition, and is best suited for common conditions, or within a targeted population for rare conditions. Examples of prospective cohorts include the Health Professionals Follow-Up Study (HPFS) and the Nursing Health Study (NHS), who were followed prospectively from 1984 to 2008 and studies of those with a history of NMSC were found to have significantly higher risk of other primary cancers.⁶ Relative risk (RR) is defined as the risk of developing one condition if the exposure is present relative to the risk of another group without exposure. An RR of 1 implies there is no difference between groups, greater than 1 implies that the condition is more common in the experimental group, and an RR less than 1 suggests that the condition is less likely in the experimental group. RR, unlike OR, demonstrates temporality.

In contrast to a prospective cohort study, a retrospective cohort study identifies individuals that had exposure in past (typically via chart review or databases) and measures outcomes at some defined time (such as study start time or a time in the future) (Fig. 11-1). Outcomes for both can be measured in RR, hazard ratio (HR), OR, standardized incidence ratio (SIR), or standardized mortality ratio (SMR).

SIR is used to determine whether incidence of disease in a small population is high or low, while SMR is a similar measure for incidence of death. For example, a retrospective cohort study design was used to examine the association between histopathologic risk factors (poor differentiation, perineural invasion, tumor diameter ≥ 2 cm, invasion beyond subcutaneous fat) and outcomes including death and nodal metastasis from 256 high-risk cutaneous SCCs.⁷ The benefit of a retrospective cohort study is that it can be conducted on a smaller scale requiring less time and resources to complete, can more easily examine multiple outcomes, as well as rare outcomes. Depending on the research question, a retrospective cohort study design may be a good approach for dermatologic surgeons performing clinical research.

Interventional studies

Clinical trials. In a randomized controlled trial, the design is experimental; the researcher has a hypothesis and participants are randomly assigned to receive an intervention versus a placebo control (whenever ethically

possible). Blinding refers to whether the participant has been blinded to his or her assigned group. A double-blind study refers to one in which both the participants and the researchers are blinded to group assignment.

The outcomes and safety measured depend on the phase of the trial. Phase I trials are early, typically unblinded, and may or may not include a control. These are simply a test of the tolerability and safety of the intervention in order to determine whether the intervention is appropriate to study further. An example of a phase I trial relevant to dermatologic surgery is the study of vismodegib, a small-molecule inhibitor of smoothened (SMO) in the Hedgehog signaling pathway, for the treatment of advanced basal cell carcinoma.⁸ These studies may investigate the pharmacokinetics of a drug and may provide guidance for dosing during a phase II trial. A phase II study is a small controlled study where both effect and safety of intervention are measured. An example of a phase II clinical trial in dermatologic surgery involved 601 patients with superficial BCC by biopsy randomized to treatment with MAL-PDT, 5-fluorouracil, or imiquimod.⁹ A phase III study is similar to a phase II study, only larger. If the intervention passes through a phase III trial, then it is possible to gain FDA approval. For example, a phase III, double-blind, randomized controlled trial was used to examine the effect of oral nicotinamide (the amide of vitamin B3) on the rate of new nonmelanoma skin cancers over a 12-month period.¹⁰ Phase IV trials are utilized after the intervention has been out on market to monitor for adverse effects and define other applications for the intervention.

All of these study examples adhere to the Consolidation Standards of Reporting Trials (CONSORT) guidelines (<http://www.consort-statement.org/>). This group offers a 25-point checklist to follow for reporting results from a clinical trial as well as a flow diagram for an example of how to report enrollment. The checklist covers all steps from study objectives, study design, to statistical analysis.

Also, prior to submission, clinical trials that have one or more sites in the United States or that test a drug or device that is manufactured in the United States or its territories must be registered with ClinicalTrials.Gov. (<http://www.clinicaltrials.gov>). International trials can be registered on the Current Controlled Trials website (<http://www.controlled-trials.com>), which is recognized by the World Health Organization. A skin-specific resource for therapeutic trials is the Cochrane Skin Group Ongoing Trials Register

(<http://www.nottingham.ac.uk/ongoingskintrials/>), aimed at informing the community of skin-specific therapeutic trials.

Quasi-experimental designs. In addition to clinical trials, variations on the randomized controlled trial interventional study design may increase the feasibility and efficiency of the study. For example, matched pair randomization design allows for subjects with baseline confounding variables to be balanced, while one member of the pair receives the intervention. Crossover designs involve switching the placebo and intervention groups during the study to account for confounding variables, assuming there is no lasting effect of the intervention.

Secondary data analysis: meta-analysis, systematic reviews

In clinical research, systematic reviews and meta-analyses represent the highest level of clinical evidence, as they are comprised of a compilation of randomized controlled or clinical trials (RCTs). Claims of the best treatment practices within dermatologic surgery are often based upon results from systematic reviews and meta-analyses. The simultaneous analysis of numerous RCTs helps to create a consensus answer for questions in dermatologic surgery. For example, a systematic review on the treatment of squamous cell skin cancer may include RCTs examining endpoints such as cure rates, recurrence, aesthetic and functional outcomes, or cost effectiveness in order to elucidate the best treatment. Results of systematic reviews are presented as streamlined and objective appraisals allowing the clinician to identify any potential biases.

Statistical tests may be used to mitigate heterogeneity of studies reviewed and assess potential bias in the small studies included. Methodological quality of included studies may be assessed using the Strengthening of Reporting of Observational studies in Epidemiology (STROBE) checklist.¹¹

Study population

The investigator must specify demographic characteristics of the target population that will practically address the research question. Establishing geographic and temporal criteria ensures that the sample is representative and that the study is feasible. Optimizing feasibility may also involve ensuring the reliable identification of the study population, as well as

sufficient sample size. A larger sample size can yield more accurate results but must be balanced by the associated costs of data acquisition and analysis. The sample size should be adequate to convey reproducible outcomes and have adequate power.

In the case where a dermatologic surgeon is evaluating the efficacy of a novel topical treatment for actinic keratoses, inclusion criteria may involve a dermatologic disease state, such as patients with a history of actinic keratoses, or may involve a more general demographic state, such as patients who are 18 years or older, obese patients, or patients with a history of tanning bed use. Determining the inclusion criteria is a balancing act; it must be broad enough to include enough subjects to impart sufficient power to the study, while staying focused to answer the specific research question. In amassing of articles for a systematic review, selection of specific search terms and an inclusion time frame of published date may represent inclusion criteria for abstracts to analyze.

Exclusion criteria may clarify the scope of a research project. Exclusion criteria may represent patient characteristics (excluding those with a history of melanoma), disease characteristics (excluding superficial type basal cell carcinomas), or study specific (exclusion of articles written in non-English languages for a systematic review).

In some cases, rigorous inclusion and exclusion criteria may select for ideal patients that fail to reflect a general population. Thus, the results of the study may not have generalizability. For instance, a trial for a targeted drug therapy for SCC may exclude patients with comorbidities, immunosuppression, or cancer. While this may help with study outcomes and decrease drop out, the average patient with SCC will have one or more of these conditions, and thus the data may not be generalizable to the general skin cancer population.

Inclusion and exclusion criteria apply to both intervention and control groups. Control groups are important in observational and interventional studies as their presence permits a clinical comparison. Without comparing a new suturing technique with the standard of care, superiority cannot be demonstrated. Matching control and intervention groups mitigate confounding. For example, having no significant difference in age, gender distribution, socioeconomic status, or baseline health status between control and intervention groups ensures that other disease processes or social determinants of health are not driving the observed difference.

Sources of electronic data available in databases and patient registries useful for identifying a study population for clinical research in dermatologic surgery are outlined in Tables 11-3 and 11-4.¹²

Table 11-3. Databases with Utility for Dermatologic Surgeons

Clinical Trials	—NASCET Study Source of precise clinical data for risk adjustment —ACAS Study and outcomes. Limited by number and types of patients, data selected for study
Prospective	—APACHE Prospective data collection, clinically precise
Observational	—MPM data, limited by biases, variables not collected, Cohorts correlation with underlying population
Registries	—SEER Prospective collection of data of patients with —UNOS specific conditions, rich clinical information, —STS patient-specific or grouped data
Administrative Databases	—Medical Record Hospital medical (electronic) record departments —Departmental quality assurance dataset
Enrollment	—Medicare Total number of eligible persons for medical beneficiary file services —State medical Source of denominator for population-based rates research file
Encounter	—National Hospital Track utilization and resource consumption, Discharge Survey describes clinical events with ICD-9-CM —VA EDR (admissions, procedures), very large sample sizes. —State Hospital May be linked to enrollment to determine rates.
Discharge Databases	—HEDIS Encounter data enriched with specific clinical survey —UHC variables, often used for benchmarking, dataset —PHC4 CABG patient-centered information

Variables of interest

The endpoint or outcome of a study is the dependent variable that answers the specific research question. Outcomes may be in the form of a surgical result (e.g., clear resection margins), a disease state (e.g., melanoma), or survival (e.g., mortality from melanoma). When a study design is

longitudinal, it is important to define the window of time in which the outcomes of interest can occur. For example, it may take decades for a patient to develop a recurrence of basal cell carcinoma after excision, though defining the endpoint of recurrence within the confined time period of 5 years may be necessary for project feasibility.

Co-variables, or independent variables, are factors that may impact the endpoint or outcomes studied, and are important sources of potential bias or confounding, and need careful consideration. They may be demographic factors (age, gender, education level, and geographic location), comorbidities (immunosuppression, autoimmune disorder), or exposures (tanning bed use, occupational exposures). Co-variables may be matched between intervention and control groups in order to elucidate whether these variables represent selection bias in a particular group.

Statistical methodology

Understanding basic statistical concepts and tools can help reduce bias from potential confounding variables and improve understanding of the application of clinical findings. Statistical analysis can be performed using one of many analysis sources (SAS, STATA), the use of which is beyond the scope of this chapter. Quantitative data are those that will be collected in most observational and experimental studies. Continuous data are measured in real numbers with intermediate values (such as a height of 62.5 cm). Discrete data are those that are real numbers without intermediate values (number of family members with a history of skin cancer).

There are various ways to identify the center of the data. Mean is the average value of the data, including the outliers, which may greatly skew the mean. The median is the value directly in the middle (or the 50th percentile) of all the data points numbered from the lowest to the highest. Outliers do not significantly affect the median. The mode is the most common value in the data-set (or the peak of a histogram). The spread of data values can be described by variance, which is the average of the squared difference between a data point and the mean. Standard deviation is the square root of the variance, and measures how close data falls from the mean. For instance, a low standard deviation means most values fall close to the mean, while a high standard deviation suggests data falls over a wide range of values. Most data will fall in a bell-shaped curve in a normal (or Gaussian) distribution.

This assumes that 68% of data will fall within one standard deviation on either side of the mean, 95% will fall within two standard deviations of the mean, and 99.7% of data points will be within three standard deviations of the mean.

The p -value is a measure of the likelihood that the result could be seen by chance. Overall, a p -value <0.05 , or less than 5%, is considered the threshold for being statistically significant; however, the lower the p -value, the more likely the result is to be true. Power reflects the number of data points or study participants needed in the study to reveal a statistically significant ($p < 0.05$) difference in outcomes between two groups. As the power increases, there is less likelihood of a false negative result since the power is 1 minus the false negative rate. In general, power $>80\%$ is considered to be statistically powerful. Prior to initiating a study, a power analysis should be performed in order to determine the minimal number of data points required to reveal a significant result. The basic information needed to calculate the sample size includes the test type (one- or two-sided), significance level (usually 0.05), desired power (1- β , or type II error, usually 0.8), and effect size estimate (an estimate of group differences based on prior clinical studies or experience). Statisticians, statistical software, and online power calculators may be used to generate sample size numbers. Without this analysis, there may be too few data points to reach an accurate conclusion, or there may be far too many participants enrolled, which poses an ethical hazard of putting patients in unnecessary harm.

Parametric tests are those used to compare means when the data are normally distributed. The most well-known parametric test is a t -test, which can be applied to continuous data with a normal distribution. The t -test used will depend on whether the groups have equal or unequal variances. A paired t -test may be used when samples are correlated, for instance, in a before-and-after study or when samples are matched pairs such as in a case-control study. Nonparametric tests are those that are used when the data-set is not normal and include the Wilcoxon Mann–Whitney U -test, Kruskal–Wallis (H) test, and Wilcoxon Signed-Rank test. A chi-squared test can be used when comparing an observed proportion compared to an expected proportion, such as comparing the incidence of nodular melanomas between sexes when compared to the expected value (50:50).

A regression analysis allows the researcher to test the effects of multiple independent variables on a given outcome. For instance, instead of simply

determining the effect of age on metastatic rate of SCC, regression analysis could determine the effect of age, immune status, therapy received, and comorbidities on the metastatic rate of SCC in that study group. Regression analysis is performed using a statistical package that models the data resulting in an r^2 -value. This value can help the reader or researcher determine how much of the variance in the outcome is due to the variables identified. For instance, if $r^2 = 0.78$, 78% of the outcome is due to the defined variables.

Logistic regression seeks to model the probability of an event occurring when the dependent variable is binary and generates an OR and p -value for any given independent variable.

TEAM-BASED APPROACH TO CLINICAL RESEARCH

Key collaborators, both in the field and in outside disciplines, may significantly help inform the research project due to their knowledge, experience, or expertise. Depending on the institution or facility, teams of researchers or other ancillary staff may be available to help in the planning process and funding. Participating in a lab-based research meeting dedicated to clinical research or presenting preliminary protocols in a lecture format can yield valuable feedback and allow for refinement of the research plan or grant application. Additionally, at many large institutions, there are networks dedicated to assisting researchers through the planning and funding process. Mentorship in dermatologic research has been associated with improved productivity and success in the form of securing grants and accepted publications.^{13,14} It may be necessary to obtain assistance from a programmer or analyst to help set up a database needed to store and analyze the study data. A project coordinator can be critical in keeping projects organized, enrollment, consent process, and Institutional Review Board (IRB) submissions. Additionally, early involvement with a statistician is recommended for those without formal epidemiologic training.

ADDITIONAL TRAINING IN CLINICAL RESEARCH METHODS

Additional preparation for undertaking clinical research in dermatologic surgery includes refining skills in areas such as study design and biostatistics. Gathering data may be time consuming, but how that data are analyzed is of paramount importance in obtaining a meaningful assessment of the outcome in question. Although it is important to be familiar with basic aspects of statistics, the utility of collaborating with a statistician or quantitative analysis, even at formative stages of the research process, cannot be understated. Statisticians are experts at determining the important aspects of the research plan, such as appropriate sample size, and open discussions of project methodology allow for feedback from a statistician in addition to suitable analysis of data. Garnering a knowledge base in these disciplines will aid the clinical researcher in facilitating collaboration with statisticians within a research team. There are numerous online resources available to help bolster knowledge of basic quantitative methods, such as the free online course offered by Harvard University's edX program entitled "Health in Numbers: Quantitative Methods in Clinical & Public Health Research" (<https://www.edx.org/course/health-numbers-quantitative-methods-harvardx-ph207x>). In addition, many institutions offer intensive short courses in biostatistics for fellows and physicians.¹⁵ Particular institutions may offer grant preparatory courses and offer feedback in a structured setting.

FUNDING AND BUDGETING

Whether a physician–scientist in dermatologic surgery dedicates the majority or a small portion of his or her career to clinical research, funding allows for increased sustainability. After a study protocol has been developed, the investigator drafts a proposal, which concisely communicates a logical outline of the study plan, and showcases the merits of the study. Senior colleagues serve as a resource for choosing a specific funding agency. The range of granting agencies for biomedical research includes governmental agencies, foundations, manufacturers of drugs and devices, professional societies, and patient advocacy groups. A list of all current US government discretionary funding opportunities can be found on the website [grants.gov](https://www.grants.gov).

Table 11-5 outlines some of the available funding opportunities for dermatologic surgeons pursuing clinical research. Affiliation with an academic institution, industry, or a professional society may afford additional access to funding sources.

Table 11-5. Funding Mechanisms for Dermatologic Surgeons Engaged in Clinical Research

Funding Category	Sources
Nongovernmental	Dermatology Foundation Skin Cancer Foundation American Skin Association
Governmental	National Institutes of Health
	Award
	F32: Individual post-doctoral fellowship

	Agency for Health Quality and Research Centers for Disease Control Department of Defense Department of Energy—Office of Science Department of Veteran Affairs National Science Foundation Office of National Drug Control Policy
Professional Society	American Society of Dermatologic Surgeons American Academy of Dermatology Society for Investigative Dermatology Women's Dermatologic Society

In addition to securing funding, establishing a budget for direct and indirect costs will help guide the plan and scope of the clinical research project. Budgeting allows for control and awareness of how funding is allocated, and establishing a budget facilitates future communication with collaborators and potential funding sources. Aspects of a clinical research budget include personnel, consultant costs, equipment, supplies, travel, patient care costs, and consortium and contractual costs. An example budget form is provided in Table 11-6; however, often specific grants will require a unique budget form.

Table 11-6. Simplified Budget Example

Expense Description	Project Role	Budgeted Funds	Percent of Total
Key personnel			
Other personnel			
Total PERSONNEL COSTS			
Equipment			
Other direct costs (i.e., travel, office supplies, IT equipment, operating costs)			
Facilities and administrative costs (indirect costs)			
Total costs			

Dermatologic surgery is unique in that many innovations stem from physician–scientists with loose or even no formal academic affiliations. In many cases, such investigations may be self-funded.

PROTECTION OF HUMAN SUBJECTS

Human subjects training

The clinical researcher has an obligation to protect the privacy and safety of subjects. The Health Insurance Portability and Accountability Act (HIPAA) of 1996 provides nationwide privacy protection for health information in the United States. The regulations set boundaries for the use of health records and all research-involving human participants is subject to review by the IRB. When enrolling in a study, patients must be told the purpose of the study, the risks and benefits, alternatives to participate, and his or her rights of confidentiality and right to withdraw from the study at any time. Each subject must provide voluntary agreement to participate by signing informed consent. Training on regulations for human subject research is available online through the Collaborative Institutional Training Initiative (CITI).

The role of the Institutional Review Board

Any research proposal that involves the use of human subjects has to be approved by an IRB. The role of the IRB is specifically stated in federal regulations regarding human research (Code of Federal Regulations, Volume 21). By law, the IRB must review all components of the research project and ensure that the following requirements are met before approving any study:

- Minimization of risks to subjects
- Assessment of risks to ensure that the risk/benefit ratio is reasonable—It is important to bear in mind that this assessment is limited to the risks and benefits for the subjects in the study, as opposed to society in general
- Equitable selection of subjects
- Overview of the informed consent process (including documentation) and assurance that consent will be obtained from all subjects, as appropriate
- Data monitoring, if appropriate, to ensure the subject's safety
- Protection of subject's privacy
- Protection of special populations who may be vulnerable to coercion (e.g., children, pregnant women, prisoners, handicapped, mentally disabled or educationally or economically disadvantaged people), if appropriate.

Finally, the IRB approval to conduct a specific research project must be updated with changes to the study protocol, and must be renewed.

For patients involved in the study, compliance with the HIPAA is necessary and informed consent is a prerequisite.

DISSEMINATING FINDINGS

The most interesting and novel of findings will not have any clinical impact if they are not disseminated and ultimately published. When choosing a journal for submission, it is important to consider the scope of the journal, its target audience, and the impact factor of the journal. It is important to look at a journal's website to make sure your paper fits in with the scope and mission. If you are not personally familiar with the journal, it is important to read recent issues to understand the types of papers that the journal and editorial board select for publication. Typically journals offer publishing guidelines for various article types and will also offer guidance for how to respond to reviewer comments. Additionally, there are published reporting criteria for the various epidemiologic formats ([Table 11-7](#)). Despite a well-planned and executed study, rejection is always a possibility and researchers should be prepared to revise the manuscript and resubmit until the proper audience is reached. There are resources that can help guide dermatologic

surgeons on approaches to addressing peer-review comments that maximize the chance of subsequent publication.^{16,17}

CONCLUSIONS

Many methods exist for examining important clinical questions in the field of dermatologic surgery. It is important to choose a study design that accurately addresses the research question and develop a protocol that will generate data needed to answer the question. Available funding and collaborative opportunities will help in the pursuit of clinical research. Regardless of years in practice or practice setting, all dermatologic surgeons have the ability to confront uncertainties in clinical practice through clinical research. Many of the high-quality surgical techniques and improvements in clinical care enjoyed by dermatologic surgeons today result from clinical research physician–scientists. Advancements in clinical research in dermatologic surgery have the ability to impact clinical practice and improve the patient and surgeon experience, and all dermatologic surgeons have the potential to become active participants in this process.

CHAPTER 12 Local Anesthesia, Regional Nerve Blocks, and Postoperative Pain Management

David T. Harvey
Emma Elizabeth Harvey

SUMMARY

- Local anesthesia is a critical component of dermatologic surgery, and allows even large flaps to be performed comfortably in an office setting.
- If patients unnecessarily undergo painful procedures, or painful anesthesia injection, this may adversely affect their overall experience and may undermine their confidence in the dermatologic surgeon.

Beginner Tips

- Lidocaine 1% with 1:100,000 epinephrine is the most widely used local anesthetic in dermatologic surgery.
- Lidocaine-allergic patients can usually be treated with either bupivacaine or, for small biopsies, normal saline or cryoanesthesia.
- Patients may complain of an “allergy” to epinephrine; on detailed history, this is often related to intravascular injection during a dental procedure, but patient preference should always be respected.
- Use physical and mental distraction liberally and always inject slowly when possible.

Expert Tips

- For Mohs surgery defects on the lower leg and other high-risk areas, consider adding dilute clindamycin to the local anesthetic.
- 0.15 cc of clindamycin 150 mg/mL is added to a 50-mL vial of local anesthetic. Risks, including allergy, should be discussed with the patient.

Don't Forget!

- Concerns regarding digital block-related necrosis due to the addition of epinephrine are probably unfounded, though volume should be minimized when possible.
- Patients should be warned that temporary paralysis may be seen postoperatively; a unilateral facial droop is almost always due to anesthetic effect rather than nerve damage.

Pitfalls and Cautions

- Buffering bupivacaine with sodium bicarbonate is contraindicated due to the risk of precipitation.

- Be cautious when using off-label or compounded topical anesthetics, as these may lead to systemic side effects.

Patient Education

- Topical anesthetics may be applied at home prior to the procedure, though for most patients, a slow local anesthetic injection coupled with distraction leads to only minimal discomfort.
- Local anesthesia is usually instant, while nerve blocks take several minutes to take effect.

CHAPTER 12 Local Anesthesia, Regional Nerve Blocks, and Postoperative Pain Management

INTRODUCTION

Local anesthesia is of critical importance in dermatologic surgery. Local anesthesia permits the performance of procedures virtually painlessly through inducing a reversible loss of sensation in a well-circumscribed area of the body. Local anesthetic agents lead to anesthesia by inhibiting excitation of nerve endings or by blocking conduction in peripheral nerves.¹ A thorough understanding of local anesthesia is, therefore, important to improve the surgical experience for both patient and dermatologic surgeon.

HISTORY

The biological effects of local anesthetics were first recorded in 1860, when Albert Niemann, a graduate student in pharmacology, isolated cocaine from the plant *Erythroxylum coca* and recorded the numbing sensation felt when the substance was placed on his tongue.² Niemann did not initially consider the use of cocaine as a surgical anesthetic. Years later, in 1884, a graduate

student in Vienna named Sigmund Freud experimented with the effects of cocaine on himself and animals. Freud published a paper called “Über Coca”³ which claimed that cocaine could be used to treat mental disorders. In 1884, Karl Koller, an ophthalmology resident and colleague of Freud, presented the idea of cocaine being used clinically and issued a paper on its use in ophthalmologic surgery.² Physicians, at first, were slow to accept the idea of using cocaine for medical purposes but eventually embraced its use. This initial acceptance was followed by scrutiny once the addictive and toxic aspects of cocaine were recognized.

In the early 20th century, several safer anesthetics were developed. In 1904, Alfred Einhorn synthesized an ester of para-aminobenzoic acid (PABA) called procaine.⁴ A year later, Heinrich Braun was the first to successfully use it as an anesthetic.² Höechst initially promoted procaine under the name Novocain, but soon found that it produced an extreme drop in blood pressure and was responsible for several deaths.⁵ To overcome this, procaine was combined with epinephrine. In 1930, a more potent PABA ester, tetracaine, was introduced⁵; unfortunately, it demonstrated a proclivity to produce allergic reactions. In 1943, Lofgren and Lundqvist^{2,4} synthesized an amide derivative of diethylaminoacetic acid called lidocaine that proved to be effective and safe.⁶ This eventually led to its mainstream use in surgery as a local anesthetic. Since the initial introduction of lidocaine, several other local-acting drugs have been developed.

STRUCTURE

All local anesthetics have similar structures and contain three parts: the aromatic ring, the intermediate chain, and the terminal amine portion (Fig. 12-1). Any alterations of the anesthetic agent can affect its pharmacological properties. The aromatic ring, a lipophobic component, is responsible for the diffusion of the anesthetic through cell membranes and nerve sheaths.⁶ The intermediate chain binds either an ester or an amide containing between three and seven carbon equivalents, and is responsible for its mode of action.⁷ Disruption of the intermediate chain is responsible for local anesthetic metabolism and the reversible nature of these agents.⁷ The amine terminus can arise in a tertiary form that is lipid soluble or a quaternary form, which is

water soluble and positively charged.⁸ It is this same terminus that is thought to bind to the sodium channel and determine the length of action of the anesthetic.⁷

Figure 12-1. All local anesthetics have similar structures and contain three parts: the aromatic ring, the intermediate chain, and the terminal amine portion.

CLASSIFICATION

Local anesthetics have two main chemical classifications,⁵ and depend on the structure of the intermediate chain: those, which contain an amide group (e.g., lidocaine), and those which contain an ester attachment (e.g., procaine). This linkage is very important to the anesthetic agent as it defines the pathway by which the molecule is metabolized and excreted.⁶

Amide anesthetics are hepatically metabolized.^{5,6} Lidocaine is considered an intermediate potent anesthetic, and has a wide range of clinical uses.⁹ It exhibits a rapid onset of action, shows no cross reactivity to ester-type local anesthetics,⁵ and is therefore safe to use in patients who are allergic to procaine or tetracaine. Lidocaine comes in 0.5%, 1%, and 2% concentrations, and lasts on average for 30 to 400 minutes.⁶ Bupivacaine is a high-potency amide anesthetic, which lasts for 2 to 6 hours.⁶ Longer-lasting effects of bupivacaine have been attributed to its slower elimination time.¹⁰ Lidocaine and bupivacaine in combination have been studied and shown to prolong mean anesthetic duration,¹¹ as is sometimes required with longer Mohs surgery procedures. A comprehensive list of amide anesthetics is shown in Table 12-1.

Table 12-1. A Comprehensive List of Amide Anesthetics

Generic	Brand
Articaine	Septocaine®
Bupivacaine	Marcaine®, Sensorcaine®
Dibucaine	Nupercainal®
Etidocaine	Duranest®
Levobupivacaine	Chrocaine®
Lidocaine	Xylocaine®
Mepivacaine	Carbocaine®
Prilocaine	Citanest®
Ropivacaine	Naropin®
Trimecaine	Mesocain®

Ester local anesthetics are metabolized by pseudocholinesterase and excreted in the urine.^{6,8} The strength and duration of these agents correlate inversely with their rate of hydrolysis.⁶ Patients with atypical¹² or low levels of pseudocholinesterases are prone to a greater risk of inadvertent toxicity.⁶ PABA is a major metabolic product of ester anesthetics, and a main reason for contact allergies.⁸ The most common types of ester anesthetics are benzocaine, procaine, tetracaine, and cocaine.⁶ The latter is a highly effective vasoconstrictor, and has been used for nasal procedures.¹³ Procaine has a rapid onset of action but shorter half-life, lasting for 15 to 30 minutes.⁶ Tetracaine is 10 times more potent than procaine and is often used as an ocular anesthetic drop.^{14,15} Chloroprocaine was developed to meet the need for a shorter-acting anesthetic agent with a favorable safety profile.¹⁶ It is licensed in Europe for procedures lasting up to 40 minutes. Although less toxic than lidocaine, it is a more painful anesthetic to administer due to its acidic pH.¹⁴

STRUCTURE AND PHYSIOLOGY

Mechanisms of action

Local anesthetics work through reversibly impeding nerve depolarization and activation by interfering with Na^+ ion movement across nerve membranes (Fig. 12-2).¹⁷ Decreased permeability of cell membranes to Na^+ ions prevents the nerve action potential from being reached. In a resting cell, intracellular electric potential is intrinsically negative compared to the extracellular space.⁶ The nerve's cell membrane and Na/K ATPase pump help maintain this natural gradient.⁶ Although the exact mechanism of sodium channel blockade is unclear, one postulate is that local anesthetics bind to a receptor located on the cytoplasmic portion of the cell membrane.¹⁸ To reach this site, the uncharged form of the anesthetic diffuses through hydrophobic pathways.¹⁴ After binding, the anesthetic induces a conformational change in the receptor and renders it inactive.¹⁹ Local anesthetics preferentially bind to activated sodium channels in rapidly firing neurons leading to what is termed a “state-dependent” blockade.^{20,21}

Figure 12-2. Local anesthetics work through reversibly impeding nerve depolarization and activation by interfering with Na^+ ion movement across nerve membranes.

Cutaneous nerve fibers vary in size and type.⁶ Larger myelinated nerves are usually more difficult to anesthetize than their smaller counterparts.⁵ There are three main categories of nerve fibers. They are referred to as A, B, and C (Table 12-2). Somatic fibers are divided into four subtypes: Alpha, Beta, Gamma, and Delta. All A fibers are myelinated,⁵ with Alpha being responsible for motor impulses and proprioception. Beta fibers are responsible for pressure and light touch, Gamma fibers for proprioception

and muscle spindle tone, and smaller Delta fibers for pain and temperature.^{6,14} B fibers are myelinated and are preganglionic sympathetic fibers.⁵ C fibers are the smallest nerves and are unmyelinated.⁵ They are responsible for conducting temperature and pain sensation in a manner similar to A Delta fibers.⁵ Due to their smaller size, nerves that conduct the sensation of pain and temperature are affected by local anesthesia before the loss of pressure, vibration, and proprioception.¹⁴ This is why patients may be able to detect light touch during procedures in which they are effectively numbed.^{5,14} It is important to understand this principle and be able to readily explain this to the patient, preferably prior to surgery, to reduce their anxiety.

Table 12-2. Nerve Fiber Types

A Fibers		
Alpha	(Myelinated)	Motor Impulses and Proprioception
Beta	(Myelinated)	Pressure and light touch
Gamma	(Myelinated)	Proprioception and muscle spindle tone
Delta (Small)	(Myelinated)	Pain and temperature
B Fibers		
	(Myelinated)	Preganglionic sympathetic
C Fibers (Small)		
	(Unmyelinated)	Pain and temperature

Anesthetic additives

Local anesthetic agents may come premixed or are compounded with additives for additional pharmacological benefits. It is important to understand how these additives work, what concentrations are safe, and how can they affect anesthesia efficacy.

Epinephrine

Epinephrine is the most common additive used in local anesthesia.⁶ It counters the local anesthetic's tendency to induce vascular smooth muscle relaxation, which can promote bleeding.⁵ Vasoconstrictive effects occur

quickly, with full effects taking 7 to 15 minutes.^{5,14} Epinephrine limits anesthetic diffusion and helps to minimize the absorption of anesthetic into the systemic circulation. It also allows less anesthesia to be used to complete the numbing process. A liability for epinephrine use is the potential for delayed bleeding once its effects wear off. Concerns for postoperative hematoma development¹⁴ should be addressed with the patient prior to surgery. Epinephrine is labeled as a Category C drug.

Sodium bicarbonate

Sodium bicarbonate is a weak base with the molecular formula NaHCO_3 . When mixed with lidocaine with epinephrine, resultant injections are notably less painful.^{22,23} Simple lidocaine with epinephrine has an acidic pH of 3.3 to 5.5,⁵ which contributes to patient discomfort. It is usual for dermatologic surgeons to “buffer” lidocaine with epinephrine with 8.4% solution of NaHCO_3 as follows: 1:10 (1 part 8.4% NaHCO_3 to 10 parts lidocaine 1% with 1:100,000 epinephrine) or 1:15 (1 part NaHCO_3 to 15 parts 1:200,000 epinephrine).⁵

Although patients experience less pain with buffered lidocaine, the addition of NaHCO_3 makes the compound less stable, resulting in a shorter-action duration.²⁴ On the positive side, the addition of NaHCO_3 allows for faster nerve membrane penetration and a quicker onset of anesthetic effect.⁷ In short, there is a “double-edged” sword when adding sodium bicarbonate to lidocaine, though many dermatologists utilize this additive because of a perceived greater benefit for the patient. Importantly, the use of sodium bicarbonate additives with bupivacaine is contraindicated due to the risk of agent precipitation.²⁵

Hyaluronidase

Hyaluronidase is an enzyme that breaks down hyaluronic acid,⁵ an acid mucopolysaccharide present in the dermis. When added to local anesthesia, hyaluronidase facilitates diffusion of the anesthetic through soft tissues. This results in a wider field of local anesthesia, faster onset of action, less tissue

distortion, and easier tissue undermining.²⁶ In ophthalmology, hyaluronidase additives allow the surgeon to minimize injection sites, decrease the volume of anesthesia used, and lessen the bruising risks for the patient.⁵ Doses in cutaneous surgery vary. Some authors recommend that 150 units of hyaluronidase be mixed in 20 to 30 mL of lidocaine for a concentration of 7.5 units/mL.²⁷

There are some risks with using hyaluronidase, including decreased anesthetic duration and a greater risk of toxicity due to enhanced absorption.²⁷ Hyaluronidase also contains the preservative thimerosal,⁵ which is a contact allergen. Preoperative skin testing in highly sensitive patients is recommended prior to its use.^{5,27} Hyaluronidase should also not be used in those with a documented bee venom allergy.²⁸

Triamcinolone

There are several advantages to combining lidocaine with a corticosteroid injectable.²⁹ This mixture is useful for treating acne cysts, keloid scars, and alopecia areata. Doses vary from 2.5 to 5 mg/mL for facial cysts to 20 to 40 mg/cc for thick keloid lesions. In orthopedic surgery, triamcinolone mixed with lidocaine serves as both a diagnostic and therapeutic tool to evaluate for rotator cuff tendonitis.³⁰

Clindamycin

Clindamycin mixed with lidocaine has been described as a way to provide antibiotic prophylaxis. One study examined 1172 wounds treated with 50 cc 1% lidocaine mixed with epinephrine, 5 mL of 8.4% NaHCO₃, and 0.15 mL of 150-mg/mL clindamycin.³¹ Culture-positive wound infections were less frequent in the clindamycin group compared to control group. No allergic reactions were reported. More data need to be evaluated before this combination is routinely recommended.

Cosmetic injectables

Many cosmetic injectables today come premixed with local anesthesia (Table 12-3). Several hyaluronic acid and calcium hydroxyapatite injectables are commercially prepared or mixed with 0.3% lidocaine.^{32,33} Poly L-lactic acid can be mixed with local anesthetic using 6 cc of sterile water and 3 cc of 1% lidocaine with 1:1000 epinephrine.³⁴ This allows for a more comfortable experience for the patient.³³ especially when correcting volume deficiencies in sensitive areas such as the lips, tear troughs, temples, and malar cheeks.

Table 12-3. Cosmetic Injectables Premixed with Local Anesthetic

Filler Name (Brand)	Type/Lidocaine Concentration
Juvederm Ultra®/ Ultra Plus®	Hyaluronic acid/0.3% lidocaine
Juvederm Volbella®	Hyaluronic acid/0.3% lidocaine
Radiesse (+)®	Calcium hydroxylapatite/0.3% lidocaine
Perlane®	Hyaluronic acid/0.3% lidocaine
Bellafill®	Bovine collagen/PMMA microspheres/0.3% lidocaine
Restylane Silk®/Lyft®	Hyaluronic acid/0.3% lidocaine
Prevelle Silk®	Hyaluronic acid/0.3% lidocaine

Microbotox uses multiple microdroplets of diluted onabotulinum toxin A injected into the superficial dermis.³⁵ The goal of this treatment is to improve skin texture, diminish oil production, smoothen horizontal creases, and decrease vertical banding of the neck. The Microbotox solution is mixed by adding a small volume of lidocaine and larger amount of preservative-free saline to onabotulinum toxin A, yielding a final concentration of 20 to 28 units of onabotulinum toxin A per milliliter of solution.³⁵ Approximately 100 to 120 injections are used to treat both sides of the face and neck (Fig. 12-3).

Figure 12-3. A. Approximately 100 to 120 injections are used to treat both sides of the face and neck: 100 markings total, 50 per side spaced 1.5 to 2 cm apart. B. Note skin blanching after intradermal injections is placed due to lidocaine with epinephrine. Decreased oil secretion and a smoother skin texture is noted after the Microbotox procedure.

Deoxycholic acid is a cosmetic injectable that is used to treat submental fullness.³⁶ It works through inducing focal lipolysis and serves to restore a more youthful cervicomental angle after two to five treatments. Deoxycholic acid induces some pain and swelling which lasts minutes to days post-injection. To make the procedure more comfortable, small volumes of local anesthetic, for example, 4 to 6 cc of lidocaine with 1:100,000 epinephrine can be injected into the submental area prior to deoxycholic acid treatment.³⁷

Mixing two or more anesthetics

Mixing two or more local anesthetics is a common practice for dermatologic surgeons.^{6,38} Several randomized controlled trials comparing mixtures of local anesthetics have been conducted.^{39,40} Combinations studied include bupivacaine and lidocaine, bupivacaine and mepivacaine, and prilocaine and ropivacaine. Evidence suggests that mixing these agents for local infiltration and nerve block anesthesia is safe. There is insufficient data to determine whether any combination results in a faster onset or longer duration of anesthesia, and no strong evidence supports the benefits of mixing anesthetics over the use of a single agent.²⁸

Topical anesthetics

Topical anesthetics play a major role in dermatologic surgical procedures.^{5,28,41} From laser hair removal to cosmetic injectables to minor skin surgery, topical anesthesia enhances patient comfort through allowing a “needleless approach” to patient numbing. The limitation of utilizing topical anesthetics is the ability of these agents to penetrate the stratum corneum.⁴² For this reason, they work better in thinner skin areas such as the oral mucosa⁵ and/or genital skin. Newer delivery systems have enhanced the rate of topical anesthetic absorption and effect.⁴³ A list of commonly used compounded and standardized topical anesthetics can be found in [Table 12-4](#).

Table 12-4. Commonly Used Topical Anesthetics in Dermatologic Surgery

Name (Brand)	Ingredients
EMLA™ Cream	2.5% lidocaine and 2.5% prilocaine
LMX™	4% or 5% lidocaine cream
Pliaglis™	7% lidocaine and 7% tetracaine
BLT	20% benzocaine, 6% lidocaine, 4% tetracaine
TAC	0.5% tetracaine, 1:2000 epinephrine, 11.8% cocaine
LET	4% lidocaine, 1:2000 epinephrine, 0.5% tetracaine
Amethocaine™ gel	4% tetracaine gel
Hurricane gel™	20% benzocaine
Lasergel™ ^a	10% lidocaine, 10% tetracaine
Lasergel plus 10/10 ^a	10% lidocaine, 10% tetracaine, 0.5% phenylephrine
Photocaine™ gel ^a	6% lidocaine, 6% tetracaine
Betacaine LA™ ointment ^a	15% lidocaine, 5% prilocaine, phenylephrine
Betacaine Plus™ ointment ^a	15% lidocaine, 5% prilocaine

Modified with permission from Sobanko JF, Miller CJ, Alster TS. Topical anesthetics for dermatologic procedures: a review, *Dermatol Surg*. 2012 May;38(5):709–721.

Topical benzocaine

Benzocaine is commonly utilized to numb mucosal surfaces. This ester anesthetic is commercially available as a spray, gel, ointment, and solution, with concentrations ranging from 5% to 20%.⁵ Benzocaine has a higher risk of contact sensitization and methemoglobinemia,^{5,6} and must be used with caution. One common benzocaine product is Hurricane gel™, a 20% gel that is useful for dental procedures and prior to administering intraoral nerve blocks. The gel is applied for 30 to 60 seconds in the desired location.⁶ Effects last for up to 15 minutes. Cetacaine™ is a compound benzocaine product that contains 14% benzocaine, % butyl amino benzoate, and 2%

tetracaine. It has a rapid onset of action and has longer-lasting effects, for example, 30 to 60 minutes.^{6,13}

Topical lidocaine

Lidocaine has been used as a topical anesthetic for many years.⁴⁰ It is commercially available as a eutectic combination product or as a solitary agent, with strengths varying from 2% to 30%.⁶ Topicaine™ is a 4% lidocaine microemulsion gel,^{6,44} which has gained some popularity. It is formulated in cooling penetrating 5% lidocaine gel composed of water, ethanol, glycerin, jojoba oil, aloe vera oil, glycerol monolaurate, benzyl alcohol, carbomer 940, and EDTA.

There is support to suggest that compounded lidocaine mixtures (lidocaine/prilocaine) may have excellent efficacy for certain skin procedures.⁴⁵ Delivery systems employing microemulsion gels have been shown to be more effective in reducing pain during cutaneous surgery procedures. LMX™ is one such product. It has a fast onset of action requiring only 30 minutes of application time prior to procedures.⁶ Studies comparing LMX 5%™ to EMLA™ show that both are equally effective for pain reduction.^{46,47} One study showed that LMX 5%™ requires a shorter application time to achieve pain control.⁴⁶

Topical tetracaine

Tetracaine is an ester anesthetic, which comes in a topical cream, gel, and solution.⁵ Amethocaine™ gel is a 4% tetracaine gel that is formulated within a lecithin vehicle, which allows for increased penetration into the skin.⁵ When applied for 60 minutes, it has proved superior to other topical anesthetics. This was supported in one study that evaluated pulsed-dye-laser patients treated with Amethocaine as determined by visual and verbal rating scores.³² Combination products using tetracaine have also been effective for skin surgery procedures as noted below.

Lidocaine tetracaine peel

The lidocaine/tetracaine (LT) combination peel consists of a 1:1 eutectic mix of 7% lidocaine and 7% tetracaine.⁵ It is constituted in a membranous matrix

in which the anesthetic mixture air-dries into a flexible membrane. This membrane is then removed just prior to procedure initiation. Application times vary, but recommendations are 20 minutes for nonablative laser treatments, 30 minutes for cosmetic injectable procedures, and 60 minutes for tattoo removal.⁴⁸ The LT peel has also been shown to be effective for cryotherapy^{5,49} and CO₂ laser resurfacing.⁵⁰ Studies comparing the LT peel with placebo and EMLA cream have shown that the LT peel may be superior.^{50,51} With respect to safety, side effects are limited to local transient erythema.⁵¹ Care must be used when applying any numbing agents around the eyes.

EMLA

EMLA is a 2.5% eutectic mixture of lidocaine and prilocaine that is packaged commercially as a cream or patch.⁵ It is one of the most common topical agents used in dermatology and available via prescription. The definition of a eutectic mixture is one in which the ingredients are formulated to melt to liquid phase at room temperature.^{41,52} In addition to the two active anesthetic agents, EMLA contains emulsifiers (polyoxyethylene), thickening agents (carboxypolymethylene), and distilled water.⁵ It has been effectively used prior to laser surgery, chemical peels, graft procedures, skin biopsies, and electrosurgery procedures.^{41,43}

To work effectively, EMLA is usually applied under occlusion with either a plastic wrap or dressing.⁶ Numbing effectiveness depends, in part, on the anatomic area being treated and the duration of the occlusion. For example, on the face, anesthesia can occur in 30 minutes or less, whereas on mucous membranes it only takes 5 to 15 minutes.⁶ Most dermatologists leave EMLA on the skin for at least 1 hour and, for more painful procedures, 2 to 3 hours with occlusion.^{5,41} The maximum effect of anesthesia is reached within 2 to 3 hours after application. EMLA penetrates 3 mm into the skin after 1 hour of application and 5 mm after 2 hours.⁴¹

Like other amide anesthetics, EMLA should be used cautiously in conditions where the skin integrity is breached, such as psoriasis and eczema.⁵³ It is contraindicated in those with liver disease and amide hypersensitivity.⁵³ Care also must be taken when using EMLA around the eyes.⁵⁴

Pharmacy-compounded topical anesthetics

Topical anesthetics are in some instances compounded by pharmacies for use in dermatology. Standardization of compounded products proves difficult because individual pharmacies use different protocols to mix various ingredients in their topical anesthetics.^{55,56} Formula standardization should be considered for compounded anesthetics, since the formulations are not regulated by the FDA and may be inconsistent.⁵⁷ As compounded anesthetics do not require clinical trials, there is a great variability in use.⁵⁶ Mixtures are usually made using various concentrations of lidocaine, Betacaine, and tetracaine.^{6,56} Care must be taken when using compounded topical anesthetics and choosing the right company to manufacture them. Particulate matter has been shown in one case to cause corneal abrasions due to issues with a particular benzocaine 20%, lidocaine 6%, and tetracaine 4% (BLT) preparation.⁵⁷ It is essential that the dermatologist develops a working relationship with a reputable compounding pharmacy and not exceeds the dosages established for traditional topical and/or injectable anesthetic agents. The use of pharmacy- compounded topical anesthetics should only be performed under the direct supervision of a physician and conservatively applied to limited body areas.

Cryoanesthesia

The use of cold as an adjunct can be very helpful in reducing the pain associated with minor procedures such as cosmetic injectables, digital blocks, and wart destruction.^{5,6,58} The placement of a cold pack for 5 to 10 seconds prior to cosmetic injectables is a rapid and inexpensive way to provide the patient with increased comfort.

Cryorefrigerant provides another source of effective anesthesia by rapidly cooling the skin.^{5,6,59} They are held 6 in from the target zone and sprayed until the treatment area turns white,⁶ usually in 4 to 6 seconds. One should wear a mask and eyewear to avoid inhaling the vaporant and to protect the eyes from inadvertent contact.⁵ Ocular exposure from cryorefrigerants and even cryotherapy has been reported to cause pigmentary alterations and scarring.^{5,60,61} Those containing ethyl chloride are flammable, so care must be taken around lasers or sources of heat.^{5,6,61} Other cooling devices that

have been used in dermatology include sapphire cooling laser tips and the Zimmer™ machine.^{5,6} The benefits of these technologies are twofold; they provide anesthesia for the patient and protect against laser-induced thermal injury and blistering. A thorough list of cooling applications is found in Table 12-5.

Table 12-5. Cooling Applications Used in Dermatologic Surgery

Ice/cool packs
Liquid nitrogen
Zimmer™ cooling device (Zimmer Medizin Systems, Irvine, CA) (forced air cooling)
Frigiderm™ (Delasco, Council Bluffs, IA) (100% dichlorotetrafluoroethane)
Ethyl Chloride™ (Gebauer Company, Cleveland OH) (50% dichlorodifluoromethane, 50% trichloromonofluoromethane)
Instant Cold Spray™ (HL Moore, New Britain, CT) (10% isopentane, 90% butane)

Data from Plotkin S: Clinical comparison of preinjection anesthetics, *J Am Podiatr Med Assoc.* 1998 Feb;88(2):73–79.

Cryoanesthesia can also be performed effectively using liquid nitrogen; for needle-phobic patients, shave biopsies may be anesthetized using a brief liquid nitrogen spray, though the dermatopathologist should be informed as theoretically freeze artifact could occur.

Iontophoresis

Iontophoresis utilizes electric current to deliver anesthetic solution into the skin without the pain of a needle.⁵ Anesthetic delivery works well, with some studies showing a 20- to 60-fold increase in lidocaine penetration.⁶² Although there is a learning curve and expense for the machinery, iontophoresis is a very effective approach to enhance numbing efficacy, especially in the pediatric population.⁶³

ANESTHETIC ADMINISTRATION

Local infiltration

Local anesthesia can be administered either intradermally or subcutaneously. Intradermal injections are superficially placed, create more tissue distortion, have a faster onset of action, and are slightly more painful.^{5,6,14} Deeply placed subcutaneous injections are less painful and create less tissue distortion than intradermal injections, but have a slower onset of action and shorter duration of action.^{5,6,14}

It is important to learn proper injection technique to make the experience most comfortable for the patient. Methods to achieve a more painless and comfortable injection experience include those listed in [Table 12-6](#).

Although studies have been conducted to evaluate pain level with different types of local anesthetics, only a few have had a sufficiently large sample size. One study found that bupivacaine with epinephrine elicited the most discomfort, and lidocaine with epinephrine the least.⁶⁴ Another prospective, randomized, double-blind study found that 3% mepivacaine and 2% lidocaine with epinephrine induced a similar amount of pain on injection, with the lidocaine group demonstrating a slightly less, though not clinically significant, amount of moderate pain reported.⁶⁵ Further studies would be helpful to explain these differences and standardize recommendations for local anesthetic use.

Table 12-6. Methods Used to Achieve a More Painless and Comfortable Injection

■ Supporting the head of the patient while numbing ■ Talking to and encouraging the patient during local administration ■ Hiding the needle from the patient's direct view ■ Playing relaxing music ■ Having the patient recline comfortably ■ Using cool compresses, ice or cryorefrigerants prior to injection ■ Applying topical anesthetics prior to injection ■ Using a smaller diameter needle, e.g., 30- or 31-gauge needle ■ Warming the solution prior to injection ■ Injecting perpendicular to the skin	■ Injecting slowly ■ Neutralizing the pH of acidic lidocaine and epinephrine by mixing (10:1) with 8.4% sodium bicarbonate ■ Employing distraction techniques such as tapping other areas of the skin while actively numbing ■ Having the patient use a squeeze toy ■ Holding the patient's hand while the injection is being performed ■ Stretching the skin taught with the nondominant hand while injecting ■ In cases where multiple punctures are required, performing needle reentry in areas previously anesthetized ■ Employing conscious sedation for small children ■ Utilization of nerve blocks or tumescent anesthesia when large areas of anesthesia are needed
--	---

Field (ring blocks)

Field (ring) blocks use local anesthesia that is injected circumferentially around the operative site.⁶ Multiple injections are required with each being placed in an area that was previously anesthetized. Ring blocks are useful in those instances where direct infiltration into the surgical site should be avoided, where nerve blocks are not an option, and for larger surgical areas. In dermatologic surgery, this approach is ideal for the excision of cysts,^{5,6} skin cancers,¹⁴ and when performing hair transplant procedures.¹⁴ It is important to inject the local anesthetic in both deep and superficial planes to optimize the numbing effect.⁵ Ring blocks conserve the total amount of anesthetic that needs to be injected. It is important to wait 5 to 10 minutes after the completion of this block to allow for adequate anesthesia and optimal hemostasis. To maximize hemostasis, the central area may be painlessly infused after completing the ring block.

Ophthalmic uses

A thorough understanding of ophthalmic anesthesia is important for the dermatologist. From laser resurfacing to lower lid blepharoplasty to ocular Mohs surgery procedures, the knowledge of how and when to use these agents is essential. The most commonly used ophthalmic anesthetics are tetracaine, proparacaine, benoxinate,^{6,66} cocaine, and lidocaine.⁶⁶ With these preparations, the anesthesia is limited to conjunctiva, cornea, and anterior sclera.⁶⁷

Tetracaine ophthalmic preparations come in concentrations ranging from 0.5% to 2%. It is administered onto the cornea and conjunctiva directly using one to two drops. The onset of anesthesia with tetracaine occurs within 30 seconds,⁴¹ and the duration of action varies from 10 to 25 minutes. It is important to let patients know that they might initially experience a slight burning sensation in their eyes, which lasts for a few seconds after the application to the globe.⁶ Tetracaine can cause keratopathy in concentrations as low as 0.5%.⁶⁸

Proparacaine is commercially available as a 0.5% solution. It is mixed with 0.2% chlorobutanol and 1:10,000 benzalkonium chloride, which are added as preservatives. Proparacaine induces less stinging than tetracaine, and has been shown to last longer (10.7 vs. 9.4 minutes).⁶⁹

EMLA cream can be used on periocular skin; however, care must be taken to avoid direct contact with the globe. There have been reports of corneal injuries after using EMLA for laser resurfacing procedures.⁵⁴ Application of EMLA has been shown to provide effective eyelid skin anesthesia prior to performing cosmetic and traditional surgery procedures.^{70,71}

Allergies to topical ophthalmic anesthetics are uncommon, and cross sensitivities are rare. Reactions usually occur after repeated administration and usually with the ester agents.⁷² These can manifest as conjunctival hyperemia, chemosis, swelling of the eyelids, lacrimation, and itching.^{68,72}

Ocular infiltrative techniques

For lower eyelid procedures involving the tarsal plate or blepharoplasty techniques, a 30-gauge 1-in needle is used. After instilling numbing drops, direct local infiltration is accomplished using buffered 1% lidocaine with 1:100,000 epinephrine.⁷³ The needle is inserted 3 to 5 mm below the tarsal plate in the middle of the palpebral conjunctival vessel arcade. The barrel of the syringe is withdrawn prior to injection to ensure that no blood vessel has been inadvertently entered, as evidenced by the absence of a blood flash in the syringe. The lower lid is stretched downward and 2 to 3 cc of anesthesia slowly injected. The infraorbital skin is gently massaged and a cool compress applied to enhance the vasoconstrictive effects of local anesthesia. After initial numbing with buffered lidocaine, 1 cc of bupivacaine 0.5% with 1:10,000 epinephrine can be added to increase local anesthesia duration.⁷⁴ This is most helpful when surgery time is expected to run 2 to 4 hours⁷⁴ as can sometimes be seen with ocular Mohs surgery or longer blepharoplasty procedures.

For upper eyelid procedures, a 30-gauge 1-in needle is also utilized. First, cool compresses are applied to the lateral orbit. Subsequently, a 2- to 3-cc buffered lidocaine bolus is administered near the lateral canthus with the needle oriented tangentially to the orbital septum. Though corneal shields are often recommended prior to numbing, they are usually not necessary for the experienced injector. The needle is advanced to a position halfway over the eyelid, and a fluid bolus is slowly injected retrograde. The newly created anesthetic bleb is then massaged medially with a cotton-tipped applicator, which expands the anesthetic over the entire length of the upper eyelid. As

with lower eyelid anesthesia, bupivacaine can be added to increase the anesthetic duration.⁷⁴

Tumescent anesthesia

Tumescent anesthesia was first described in the 1970s.⁷⁵ This important development was a major one in medicine because it allowed surgeons to deliver large volumes of local anesthesia in a safe fashion.⁷⁶ As opposed to concentrated lidocaine solutions, the tumescent anesthesia technique allows the surgeon to safely use up to 55 mg/kg lidocaine in one operative session.^{6,28,77} corresponding to injection volumes ranging from 50 to 4000 mL. The main constituents of tumescent anesthesia are normal saline, lidocaine, sodium bicarbonate, and epinephrine.^{6,78} Dilution recipes vary from 0.25% to 0.3% concentrations and are adjusted based on the type of procedure being performed (Table 12-7).

Table 12-7. Tumescent Anesthesia Recipes for Various Skin Procedures

Area	Indications	Formula
Face, neck	Thermi RF™, lipo, lifts, laser resurfacing	Xylocaine 1% plain—75 mL, 8.4% NaHCO ₃ —2.5 cc, epinephrine 1:1000—1 cc, volume 250 cc
Scalp	Flaps, hair transplants	Xylocaine 1% plain—75 mL, 8.4% NaHCO ₃ —2.5 cc, epinephrine 1:1000—1 cc, volume 250 cc
Abdomen	Liposuction, flaps, Thermi RF™ tightening	Xylocaine 1% plain—150 mL, 8.4% NaHCO ₃ —10 cc, epinephrine 1:1000—1 cc, volume 1000 cc
Back	Flaps, lipoma removal	Xylocaine 1% plain—75 mL, 8.4% NaHCO ₃ —2.5 cc, epinephrine 1:1000—1 cc, volume 250 cc
Hips, thighs, legs	Liposuction, RF, vein ablation	Xylocaine 1% plain—100 mL, 8.4% NaHCO ₃ —10 cc, epinephrine 1:1000—1 cc, volume 1000 cc
Arms	Liposuction, Thermi RF™ tightening	Xylocaine 1% plain—150 mL, 8.4% NaHCO ₃ —5.0 cc, epinephrine 1:1000—1 cc, volume 500 cc

Tumescent anesthesia has been widely used in dermatologic surgery for liposuction procedures, hair transplants, facelift procedures, scalp flaps, large tumor removals (e.g., lipomas, sarcomas), infiltrative RF procedures, and laser/RF varicose vein treatments.^{5,6,74} It is administered slowly using a pumping device or large syringe. Large multiport cannulas or 18- to 20-gauge blunt-tipped spinal needles are often used to deliver the anesthesia.

For a more comfortable injection, ice packs and blebs (0.5 to 1 cc) of 1% buffered lidocaine are used in the specific area(s) to be anesthetized. The surgeon infiltrates into these blebs slowly at first, and subsequently increases the speed of infiltration as patient comfort allows. Warming the tumescent

mixture to 104°F or 40°C has also been shown to reduce the patient discomfort.^{6,79}

The value of tumescent anesthesia in dermatologic surgery patient is that (1) it is a safe and effective way to provide local anesthesia, (2) it serves to minimize bleeding,⁷⁷ and (3) it eliminates the need for general anesthesia.⁷⁶ There is also an added benefit of a prolonged anesthesia effect^{80,81} that occurs when the tumescent mixture is slowly released into the bloodstream from deeper subcutaneous tissues.

Neck tumescent anesthesia is useful for liposuction,⁸² laser lipolysis,⁸³ RF tightening, skin resurfacing, and large flap procedures.^{6,84} To properly tumesce the neck, the patient is first thoroughly prepped with Betadine™ or Chlorhexidine™, and sterile drapes are placed. The patient's neck is slightly extended for proper visualization, and three blebs of 1 cc of buffered lidocaine are placed in the right infra-auricular crease, submental crease, and left infra-auricular crease. A small 2-mm punch or stab incision is placed in these same areas. A 20-gauge spinal needle or infiltrating cannula delivers the anesthesia. Slow and deliberate infusion is performed, with care taken to inject superficial to the platysma muscle. The neck is divided into the right, central, and left submentum (Fig. 12-4). To ensure complete numbing, the targeted area of tumescence should reach 1 cm beyond the planned treatment area. Usually, 150 to 500 cc of tumescent solution is required for complete anesthesia.^{82,85} After 20 to 30 minutes,⁷⁷ the patient should be ready for surgery with the anesthetized area appearing blanched and feeling soft and smooth.

Figure 12-4. The neck is divided into the right (*blue*), central (*green*), and left (*red*) submentum.

NERVE BLOCKS

Nerve blocks are extremely useful in dermatologic surgery. They help to optimize patient comfort,¹⁴ minimize tissue distortion,⁶ and enhance patient safety.⁶ Nerve blocks require an in-depth understanding of human anatomy and can be difficult to learn for the novice. Patience and persistence are necessary for the surgeon trying to master the art of nerve blocks. They are

especially useful for skin procedures of the head and neck, digits, foot, genitals, hand, and lateral thigh regions.^{5,6}

Nerve blocks require fewer needlesticks to achieve anesthesia.⁶ Selectively using combinations of lidocaine and bupivacaine allows for enhanced anesthetic duration and safety. Sometimes, additional epinephrine or a tourniquet is necessary to enhance hemostasis.⁶ Some authors have historically suggested that the use of epinephrine in the digital region poses a risk and should be avoided,⁵ though the consensus now is that epinephrine is safe for properly performed digital blocks.^{86,87} The risks associated with nerve blocks are rare, but can include direct nerve injury, pain, dysesthesia, neurapraxia, infection, and vessel trauma,^{6,88} which can cause unwanted bruising and/or hematoma formation.^{74,89}

To perform a nerve block, a 30-gauge ½- or 1-in needle is used. It is important to slowly advance the needle and to aspirate before injecting to avoid direct injection into a blood vessel.⁶ The use of topical anesthetics, cryorefrigerants, or distractive vibratory⁹⁰ tapping at sites distant to the nerve block area can help with patient comfort. Once the needle is placed in the correct location, small amounts of anesthetic are injected and allowed to diffuse strategically. Nerve size and type tend to correlate with the time to numb.⁹¹ Once a nerve block has been administered, it is important to wait for at least 5 to 10 minutes before proceeding with surgery.^{5,6} Repeat injections are sometimes required to complete the block. Patients should be made aware of this before starting their procedure.

HEAD AND NECK NERVE BLOCKS

The head and neck areas of the body have a vast array of nerve and blood vessel structures. The trigeminal nerve (cranial nerve V) and cervical plexus are responsible for the majority of sensory innervation for these areas (Fig. 12-4).^{5,92} The trigeminal nerve can be divided into three main components. These include the ophthalmic branch (V1), maxillary branch (V2), and mandibular branch (V3).^{5,6,92} They are responsible for sensation to the forehead, cheeks, conjunctiva, teeth, lips, nose, and chin. There are specific facial landmarks, which serve to identify where to inject anesthetic to numb

certain regions of the face (Fig. 12-5).⁹² The cervical plexus¹⁰⁹ supplies sensory innervation to the ear, neck, jaw, and posterior scalp.^{5,92} This plexus emanates from the anterior rami of four superior cervical nerves.⁵ Knowledge of their emergence points is helpful to correctly anesthetize the posterior auricle and angle of the jaw.

Figure 12-5. There are specific facial landmarks, which serve to identify where to inject anesthetic to numb certain regions of the face. The supratrochlear (1) and supraorbital (2) nerves, the latter of which emanates from the supraorbital foramen (*blue*) supplies sensation to much of the forehead. The infraorbital nerve (3) exits from the infraorbital foramen depicted in *red*. It is located 1 cm below the infraorbital rim and is responsible for innervation of the upper lip and medial cheek. Finally, the mental foramen, seen in *green*, is the exit portal for the mental nerve (4), which innervates the lower lip and chin.

Supraorbital and supratrochlear nerve blocks

The supraorbital and supratrochlear nerves provided sensation to the ipsilateral forehead and scalp (Fig. 12-6).⁵ They arise from the ophthalmic branch of V1.^{6,15,92} The supraorbital nerve emanates from the supraorbital notch, which is located on the superior orbital rim near the mid-pupillary line.⁵ The supratrochlear nerve is located about 1.2 to 1.7 cm medial to this notch.⁵ Both nerves can be blocked simultaneously by palpating the notch, gently pinching up on the skin, and injecting 1 to 2 cc of local anesthetic toward the midline.^{14,92–94} Care must be taken to aspirate before injecting to avoid inadvertent trauma to the supraorbital and supratrochlear arteries, which run medial to these nerves. The use of cool compresses before injection can also help to minimize this risk by inducing transient vasoconstriction.

Figure 12-6 . The supraorbital and supratrochlear nerves provide sensation to the ipsilateral forehead and scalp.

Figure 12-7. Auriculotemporal (AT) nerve block. The AT nerve provides sensory innervation to the ipsilateral anterior ear and temple, and is another branch of V3. It can be blocked, with mouth open, by palpating the TMJ and injecting just superior to the joint pivot point using 2 to 3 cc of anesthetic.

Infraorbital nerve block

The infraorbital nerve provides sensation to the ipsilateral lower eyelid, nasal sidewall, upper lip, and medial cheek (Fig. 12-6).^{5,6,14,92} It derives from the maxillary branch of V2 and is the largest branch of the maxillary nerve.⁶ Its exit onto the face occurs at the infraorbital foramen, which can be palpated as a notch just medial to the mid-pupillary line, approximately 1 cm below the infraorbital rim.^{6,14,92}

The infraorbital nerve can be anesthetized either percutaneously or intraorally.⁶ The intraoral approach is considered less painful.^{6,14} With this blocking technique, the maxillary gingival sulcus lateral to the canine may be topically numbed¹⁴ with 20% benzocaine left in place for 1 minute. A small bleb of buffered lidocaine is subsequently placed using a 30-gauge 1-in needle; given the minimal pain associated with this procedure, topical anesthesia is not required. After 10 to 15 seconds, the needle is advanced tangentially above the maxillary periosteum toward the notch. After negative aspiration, 1 to 3 cc of anesthetic is slowly injected. Gentle movement of the lateral upper lip with the nondominant hand can reduce discomfort as the

injection is administered. The percutaneous route, like the supraorbital block, is performed by palpating the notch of the foramen, gently pinching up on the skin, and slowly injecting a similar small amount of anesthetic solution. Topical numbing agents and/or cool compresses can be employed with the percutaneous approach to optimize patient comfort.

Anterior ethmoidal (external nasal) nerve block

The external nasal nerve is a branch of the anterior ethmoidal nerve and is located between the upper lateral nasal cartilage and lower border of the nasal bone.⁵ Anesthesia of the ipsilateral nasal tip, columella, and nasal dorsum⁵ is obtained by injecting 1 to 2 cc of anesthetic at a point between the mobile cartilage and fixed nasal bone periosteum.⁹² One way to make this block less painful, as is performed with full-face laser resurfacing cases, is to start with the supraorbital nerve block and gradually advance the anesthesia medially toward the nasal root and lateral mid-nasal sidewall. This may allow for a much better experience for the patient.

Mental nerve block

The mental nerve provides sensation to the ipsilateral chin and lower lip, including gingiva and mucosa.^{5,14} It is the terminal branch of the mandibular nerve (V3) and emerges from the mental foramen^{6,14} at a point 2.5 cm lateral to midline of the chin.^{5,6} With time, as the mandible recedes, the location of the foramen shifts to a point closer to the upper mandibular margin.^{5,92}

Like the infraorbital nerve block, the mental nerve block can be performed either intraorally or percutaneously.^{5,6} The intraoral approach is considered less painful and uses topical benzocaine gel applied to the gingival sulcus between the first and second premolars.⁵ After 60 seconds, a small bleb of buffered lidocaine is placed using a 30-gauge 1-in needle. To achieve an effective block, 1 to 3 cc of anesthetic is administered per side.

Auriculotemporal nerve block

The auriculotemporal (AT) nerve provides sensory innervation to the ipsilateral anterior ear and temple and is another branch of V3.⁶ Its course runs deeper and posterior to the temporomandibular joint (TMJ) before it exits superficially to join a course parallel with the superficial temporal artery.⁶ The AT nerve can be blocked with mouth open by palpating the TMJ and injecting just superior to the joint pivot point using 2 to 3 cc of anesthetic (Fig. 12-7).^{5,6,92}

Transverse cervical and greater auricular nerve blocks

The transverse cervical and greater auricular nerves provide sensation to the posterior auricle, angle of the mandible, and anterior neck.^{6,93} The greater auricular nerve follows the course of the external jugular vein and innervates the posterior auricular area and ipsilateral angle of the jaw.⁶ The transverse cervical nerve is located 1 cm inferior to the greater auricular nerve and migrates anteriorly, providing sensation to the ipsilateral central mandible and anterior neck.^{6,93} Both nerves derive from the cervical plexus and emerge at a well-recognized landmark known as Erb's point.^{5,6} To help accentuate accurate injection into this area, the head can be turned 45 degrees against resistance.^{5,6} Once Erb's point is identified, 2 to 3 cc of local anesthesia is injected.⁹² This will result in the numbing of both nerves and an effective field of anesthesia prior to surgery.

EXTREMITY NERVE BLOCKS

Nerve blocks for the extremities are also valuable to know and understand. They are quite effective for hand, foot, and digital numbing,^{5,6} and are excellent for nail avulsion, wart treatment, and bunion surgery. The following will review some of the common extremity nerve blocks that are used in dermatologic surgery.

Digital blocks

Digital blocks are effective for numbing the nails, toes, and fingers.^{5,6} The fingers are innervated by two ventral and two dorsal nerves¹⁴ that run lateral to the digit and usually follow the course of the palmar and dorsal digital arteries (Fig. 12-8).⁶ Proper technique allows the nails and fingers to be rapidly anesthetized. As previously mentioned, the use of epinephrine for digital blocks is no longer controversial as several studies have shown it to be safe.^{86,87}

Figure 12-8. The fingers are innervated by two ventral and two dorsal nerves that run lateral to the digit and usually follow the course of the palmar and dorsal digital arteries.

Several digital blocks are available. The most commonly used approach for nail surgery is the distal digital (“wing”) block. Its advantages are a quick onset of anesthesia, the use of smaller volumes of anesthetic, and a tumescent effect providing hemostasis. A dorsal approach to finger anesthesia is considered less painful.^{5,38} Lidocaine 1% to 2%, buffered, or ropivacaine 0.25% are appropriate choices for this indication. 0.5 mL of anesthetic is injected into a point 5 mm proximal and lateral to the junction of the proximal and lateral nail folds on each side of the digit. If a surgeon chooses to use epinephrine in their anesthetic, there should be minimal risk of intra-arterial injection due to the small caliber of arterioles in this anatomic location. If using lidocaine, then the addition of bupivacaine 0.25% to 0.5% will prolong anesthesia for up to 8 to 12 hours.

The proximal digital block is of slower onset, and up to 20 minutes may be needed before the complete numbing of the distal tip of the digit takes place. Unlike the distal digital block, it carries a potential risk for damage to the neurovascular bundles. A cryorefrigerant, cold air,⁹⁵ or topical anesthetic cream is first applied over the proximal MCP joint at two points lateral to the digit. Approximately 1 mL of anesthetic is injected laterally at the level of the metacarpophalangeal or metatarsophalangeal joints into each side of the digit. Care should be taken to draw back on the syringe before injection to avoid injecting into an arteriole of the common digital artery.

The transthecal block is a useful approach for surgery of fingers two, three, and four. Due to anatomic variation, this approach is not advised for surgery on any other digit. Its advantages are rapid onset (2 to 5 minutes) and the absence of risk to neurovascular bundles, as the needle is inserted on the palmar aspect of the digit. A rare complication is injury to the flexor tendon that can result in scar or trigger finger.

A digital tourniquet is often employed for additional vasoconstrictive effects. Tourniquet time should be limited to 15 minutes⁵ with no more than 8 cc of anesthesia administered per digit in one setting.^{5,14}

Hand and wrist blocks

Nerve blocks of the hand and wrist are useful, especially given that multiple injections are required in this sensitive area,⁵ and topical anesthetics do not work well.⁶ The median, ulnar, and superficial radial nerves provide sensory innervation to hand and wrist.⁵

The median nerve provides sensation to the first three-and-a-half fingers on the palmar side, and dorsal second, third, and medial fourth digits (Fig. 12-9).⁵ It is located between the palmaris longus and flexor carpi radialis tendons.⁹⁶ The injection site for the median nerve is located just below the proximal wrist.^{6,96,97} A needle is advanced just medial to the palmaris longus tendon under the flexor retinaculum, and 3 to 5 cc of local anesthetic is used to numb the radial side of the palm.^{6,96} As always, it is important to avoid intra-arterial injection when administering anesthesia.⁹⁷

Figure 12-9. The median nerve provides sensation to the first three-and-a half finger on the palmar side, and dorsal second, third, and medial fourth digit.

The ulnar nerve provides sensory input to both the palmar and dorsal sides of the fifth, and lateral half of the fourth digit (Fig. 12-10).⁵ The nerve runs deep to the flexor carpi ulnaris tendon and inserts into the pisiform bone.^{96,97} The ulnar block is placed lateral to the flexor carpi ulnaris tendon on the proximal wrist crease.⁵ Again, careful injection technique is important because the nerve runs just medial to the ulnar artery.⁹⁷ The second approach is to administer the block proximally at the elbow (Fig. 12-13) between the epicondyle of the humerus and the olecranon process.^{96,97}

Figure 12-10. The ulnar nerve provides sensory input to both the palmar and dorsal sides of the fifth, and lateral half of the fourth digit.

The radial nerve provides sensory input to two-thirds of the dorsal hand (Fig. 12-11).⁵ It runs just lateral to the radius and follows a course extending from the wrist to the PIP joint of the second, third, and fourth, and dorsal side of the first digit.⁵ The radial block is performed by injecting lateral to the radial artery and deep to the flexor carpi radialis tendon.⁹⁶ It is an effective way to provide anesthesia to the palmar surface of the thumb.⁶

Figure 12-11. The radial nerve provides sensory input to two-thirds of the dorsal hand.

Foot and ankle blocks

The posterior tibial, saphenous, sural, and superficial and deep peroneal nerves mediate sensory innervation to the foot and part of the ankle.⁵ A thorough understanding of their anatomic routes is important.

The posterior tibial nerve innervates the majority of the plantar surface of the foot, except for its medial aspect.⁶ It is anesthetized at the medial malleolus,⁵ where the nerve runs posterior to the posterior tibial artery (Fig. 12-12). The injection is performed with the patient resting supine and the foot externally rotated.^{98,99} 3 to 5 cc of local anesthetic is injected at the upper portion of the medial malleolus and anterior calcaneal tendon.^{5,99}

Figure 12-12. The posterior tibial nerve innervates the majority of the plantar surface of the foot, except for its medial aspect and is anesthetized at the medial malleolus, where the nerve runs posterior to the posterior tibial artery.

The saphenous nerve innervates the medial aspect of the plantar foot (Fig. 12-13). It travels along the medial calf, anterior to the medial malleolus and medial to the saphenous vein.⁵ The block is performed by injecting 3 to 5 cc of anesthetic anterior to the medial malleolus and medial to the saphenous vein.^{6,98}

Figure 12-13. The saphenous nerve innervates the medial aspect of the plantar foot.

The sural nerve is responsible for innervating the lateral aspect of the distal ankle and plantar foot (Fig. 12-13). It traverses laterally and more superficial than the posterior tibial artery, passing between the Achilles tendon and lateral malleolus on its way to the foot.⁵ To block the sural nerve, 3 to 5 cc of local anesthetic is injected between the posterior distal tip of the lateral malleolus and Achilles tendon (Fig. 12-14).^{99,100}

Figure 12-14. To block the sural nerve, 3 to 5 cc of local anesthetic is injected between the posterior distal tip of the lateral malleolus and Achilles tendon.

The superficial and deep peroneal nerves arise from the common peroneal nerve (Fig. 12-15).⁵ The superficial peroneal nerve runs initially deep along the anterolateral ankle and then splits superficially into dorsal digital nerves of all but the first web space of the foot.^{5,6} It is blocked by injecting 3 to 5 cc of local anesthetic between the anterior tibial surface and lateral malleolus (Fig. 12-14), providing anesthesia to the majority of the dorsal foot.^{6,98} The deep peroneal nerve innervates the first web space of the foot,^{5,6,101} and is located lateral to the extensor hallucis longus tendon and dorsalis pedis artery.⁶ It is a rarely blocked nerve because anesthesia to this area can be achieved by local infiltration.^{5,6} If a deep peroneal nerve block is required, then 3 cc of anesthetic is injected medial to the dorsalis pedis artery and lateral to the extensor hallucis longus tendon (Fig. 12-14).^{6,99}

Figure 12-15. The superficial and deep peroneal nerves arise from the common peroneal nerve.

ADVERSE REACTIONS

Local adverse reactions

Adverse reactions to local anesthesia vary in presentation; many reactions are due to improper technique¹⁴ or to added epinephrine,⁵ rather than to the anesthetic itself. Swelling, bruising, pain, and temporary disfigurement are some of the most frequently seen adverse reactions.^{5,14} Most resolve spontaneously without serious repercussions for the patient.

The use of epinephrine in local anesthetics has been reported to be associated with ischemia in digital areas.^{6,87} Those who suffer from collagen vascular disorders, vasospastic diseases, peripheral vascular disease, or uncontrolled hypertension are at somewhat higher risk.^{87,102} Digital ischemia

has been reported to occur when larger volumes of anesthesia are used even without the addition of epinephrine.¹⁰² Reversal can be achieved with topical nitroglycerin and/or injectable phentolamine 0.5 mg/mL.^{6,87} The latter is an alpha-adrenergic blocker that induces vasodilation.⁶

Vascular compromise has also been reported after using cosmetic filler agents containing local anesthetics.¹⁰³ Skin necrosis can occur with cosmetic injectables administered in the vascular areas of the glabella, nasal ala, and periocular areas, and it is important to be careful when injecting into these delicate areas.^{103,104} The use of cannulas and a retrograde injection technique can minimize the risk of vascular compromise. If ischemia occurs, pain or blanching of the skin is immediately noted. If not quickly treated, pain, cutaneous ulceration, and mottling of the skin can ensue.¹⁰³ A postcosmetic filler injectable kit (Fig. 12-16) containing hyaluronidase, topical nitroglycerin, thermal warm pack, aspirin, and 27-gauge needle with attached syringe can be helpful to treat such complications,^{103,104} and should be readily available for dermatologists who perform cosmetic injectable procedures. Importantly, these reactions are generally to the filler material rather than its associated anesthetic.

Figure 12-16. Filler complication kit.

Another rare complication is nerve damage.^{5,6,105} This reaction often results from block procedures where the nerve is injured from transection of the sheath, pressure from large volume of anesthesia, direct injection of anesthetic into the nerve, toxicity of the anesthetic agent, or vascular compromise to the nerve structure itself. Pain or paresthesia directly around or distal to the injection site is an early sign that a nerve injury may be occurring.⁶ If a patient complains of similar symptoms, then the procedure should be immediately stopped⁵ and patient promptly evaluated.

Chemical burns may be seen with the use of topical anesthetics, especially around the eyes.⁶ Many topical anesthetics such as EMLA have an alkaline pH.⁶ This allows for easier penetration into the skin. Ocular injuries such as corneal abrasions, ulcerations, erythema, and infections have been reported with the use of these agents.^{6,54} It is important to have an eyewash station immediately accessible in case a patient complains of eye burning or tearing from topical anesthetics. An immediate ophthalmologic assessment is important⁶ in order to minimize both ocular pain and the risk of permanent blindness.

Finally, thermal injuries can be seen after procedures that utilize tumescent anesthesia and/or nerve blocks.⁶ Burns from cigarettes and other sources of heat have been reported in patients postoperatively who do not realize that they are still numb.^{6,106,107} It is important to educate patients about the duration of their anesthesia prior to discharge from the office in order to minimize the likelihood of this adverse reaction.

Systemic reactions

Systemic reactions can also occur with topical and local anesthesia. Life-threatening adverse reactions are thankfully rare.^{5,6,108} The most common reactions usually involve the central nervous and cardiac systems. One of the most common reactions to local anesthetics is a vasovagal response.^{5,7} This is a psychogenic reaction that occurs in response to a patient's general anxiety, fear of needles, pain, or blood. Increased parasympathetic output leads to vagal-induced bradycardia, nausea, diaphoresis, lightheadedness,

and hypotension.^{5,6} Reversal is accomplished with Trendelenburg positioning,^{6,109} cool compresses, fluid intake, hand grip and leg crossing, smelling salts, and rarely midodrine or beta-blockers (Table 12-8).¹⁰⁹

Table 12-8. Treatment of Vasovagal Reaction

■ Place in Trendelenburg position ■ Smelling salts ■ Cool compresses on neck and face ■ IV hydration ■ Consider beta-blockers, midodrine ■ Leg compression ■ Patient education on how to respond to these reactions, especially if they experience “prodromal” symptoms ■ Training exercises “Applied Tension”—tensing muscles in arms, legs, and torso	■ Increase salt and fluid Intake to increase blood volume (e.g., sports drinks) prior to procedure ■ Moving/crossing legs and tightening muscles to keep BP from dropping prior to performing procedure ■ If a cardiac arrhythmia is found, implantation of a pacemaker may be needed

Table 12-9. Recommended Doses of Lidocaine

Patient Category	Maximum Dose (mg/kg)
Children	
Lidocaine with epinephrine	3.0–4.5
Lidocaine without epinephrine	1.5–2.0
Adults	
Lidocaine with epinephrine	7.0
Lidocaine without epinephrine	4.5
Tumescent anesthesia	55

Data from Avram MR, Avram MM, Ratner D: *Procedural Dermatology*. China: McGraw-Hill Education; 2015.

Lidocaine toxicity

The recommended maximum doses of lidocaine without epinephrine is 4.5 mg/kg; with epinephrine 7.0 mg/kg; and 55 mg/kg with tumescent lidocaine solutions (Table 12-9).^{6,28,77} It is essential that the dermatologic surgeon recognizes that higher blood levels of lidocaine can be attained from inadvertent vascular injection or rapid drug absorption, for example, in mucous membrane areas.⁵ Similarly, one also must be aware that local anesthetic effects in fair individuals with red hair are difficult to establish.

Some authors postulate that this may be due to a mutation in the melanocortin-1 receptor which may affect neuromodulatory regulation within the central nervous system.¹¹⁰

Lidocaine metabolism can also be affected by pseudocholinesterase deficiency, liver disease, and interactions with certain medications.^{5,6,14} Lidocaine is an amide anesthetic and is metabolized by the hepatic cytochrome CYP3A4 and CYP1A2 enzymes.^{5,6} The use of large lidocaine doses in patients taking medications that inhibit these enzyme systems can lead to an increased risk of toxicity. Common medications including tetracycline, cimetidine, SSRIs, and fluconazole inhibit CYP3A4, resulting in increased lidocaine levels (Table 12-10).⁶ Beta-blockers can increase lidocaine levels by reducing cardiac and hepatic blood flow.⁶ With respect to renal function, no special adjustments need to be undertaken when administering lidocaine.⁶

Table 12-10. Drugs Causing Elevated Lidocaine Levels (Cytochrome p450-3A4 Inhibitors)

■ Amiodarone	■ Methylprednisolone
■ Azoles (Fluconazole, Itraconazole)	■ Metronidazole
■ Carbamazepine	■ Nicardipine
■ Cimetidine	■ Nifedipine
■ Clarithromycin	■ Pentoxifylline
■ Chloramphenicol	■ Propofol
■ Cyclosporine	■ Propranolol
■ Danazol	■ Quinidine
■ Dexamethasone	■ SSRIs
■ Diltiazem	■ Tetracycline
■ Erythromycin	■ Terfenadine
■ Isoniazid	■ Thyroxine
■ Methadone	■ Valproic acid
	■ Verapamil

Signs of lidocaine toxicity

Lidocaine toxicity occurs in a concentration-dependent fashion (Table 12-11). At lower levels (3 to 6 µg/mL), toxicity may manifest as circumoral paresthesia, euphoria, anxiety, talkativeness, or blurred vision.⁶ As toxicity progresses (5 to 9 µg/mL), vomiting, tremors, and restlessness ensue.^{5,6,28,111} At higher levels of 10 to 26 µg/mL, seizures, cardiopulmonary depression, and cardiac arrest can ensue.^{6,108}

Table 12-11. Lidocaine Toxicity Based on Blood Serum Values

Stage	Serum Lidocaine Concentration (µg/mL)	Adverse Effects
I	1–6	Circumoral paresthesia, tinnitus, lightheadedness, agitation, talkative, drowsy, disoriented, metallic taste in mouth
II	6–12	Nausea, vomiting, muscle twitching, tremors, nystagmus, blurred vision, seizures
III	Greater than 12	Coma, respiratory arrest, dysrhythmia, cardiac arrest

When lidocaine toxicity begins to manifest, immediate cessation of drug delivery and basic steps to support the airway and circulation must be undertaken.^{5,6} After activating EMS and preparing for possible hospital transport, the initial management plan should be to stop anesthetic delivery, monitor vital signs, maintain ventilation, administer oxygen, and establish an IV line.⁶ Hypoxia and acidosis decrease the threshold for seizure induction and increase cardiotoxic effects.¹¹² Seizures are treated with diazepam, propofol, or thiopental sodium.¹¹² Hypotension is addressed by administering fluid boluses and sometimes adding vasopressors such as epinephrine or phenylephrine.¹¹² Bradycardia may require atropine or inotropic agents. When intubation is required, neuromuscular blockers such as succinylcholine

are often employed.¹¹² An algorithm reviewing the management of local anesthetic- induced systemic toxicity is outlined in Table 12-12.¹¹²

Table 12-12. Algorithm to Treat Lidocaine Toxicity

Bupivacaine toxicity

Bupivacaine is more cardiotoxic than other anesthetic agents and has a greater tendency to induce arrhythmias that are refractory to defibrillation.¹¹² This may be because it enters the sodium channel rapidly but leaves slowly.⁵ It also has the greatest propensity for inducing seizures.¹¹² In late trimester pregnancy, cardiotoxicity is more likely due to reduced venous return and increased progesterone levels.^{5,6,7}

Topical anesthetic systemic toxicity

There have been reported adverse effects and even fatalities with the use of topical anesthetics.^{28,113,114} Prolonged application with and without occlusion, use of inappropriately high concentrations, and application to large surface areas increase the risk of cardiotoxicity and central nervous system toxicity.¹¹³ Usually, the central nervous system is more readily affected by the pharmacological actions of local anesthesia than the

cardiovascular system.¹¹⁵ As with injected anesthetics, the initial symptoms of topical anesthetic toxicity include lightheadedness, circumoral numbness, diplopia, and tinnitus.¹¹³

With respect to reported fatalities from topical anesthetics, most reported subjects were young and received topical anesthesia prior to laser hair removal.^{6,116–118} Anesthetic application was performed under occlusion for an extended time. Two cases occurred after using compounded creams that were liberally applied to the legs^{6,116,117} for greater than 60 minutes under occlusion. Another case involved topical anesthetic application to the back.¹¹⁸ In some instances, no physician supervision was present, the patients applied the creams themselves, and no pre- and postoperative instructions were reviewed with the patient.

Rapid recognition of anesthetic toxicity is the most important step in managing an accidental overdose. If suspected, the anesthetic must be immediately washed off.¹¹³

Epinephrine toxicity

Concentrations of epinephrine greater than 1:100,000 have been reported to induce a higher rate of serious adverse events.^{5,8} The maximum dose of epinephrine that one can receive should not exceed 1 mg (1 mL of 1:1000 solution) over a 10-hour period.⁵ The dermatologist should be aware of any patient health risks, such as hyperthyroidism and cardiac disease, which can affect the metabolism and/or sensitivity to epinephrine.^{6,14} The most common side effect of epinephrine is transient tachycardia.^{14,119} This can progress, in rarer instances, to palpitations, sweating, tremors, pallor, and chest pain.^{14,120} Most of these adverse effects occur within 1 to 4 minutes after injection.^{14,119}

With respect to pregnancy, animal studies have shown that there is a reduction in uterine blood flow after epinephrine administration.^{5,121} Epinephrine is classified as a Category C drug.^{5,6,28,122} Pregnancy is considered a relative, though not absolute, contraindication to its use.⁵ Nonemergent usage should probably be delayed until after delivery.^{5,28,123} Absolute contraindications to epinephrine use include pheochromocytoma,

uncontrolled hyperthyroidism,⁵ and severe hypertension.⁶ A list of relative and absolute contraindications to epinephrine use can be found in Table 12-13.

Table 12-13. Absolute and Relative Contraindications to Epinephrine Use

Absolute Contraindications		Relative Contraindications	
Severe Hypertension		Beta-Blocker Administration	MAO Administration
Uncontrolled hyperthyroidism		Tricyclic antidepressant administration	Phenothiazine administration
Pheochromocytoma		Peripheral vascular disease	Unstable cardiac disease
Anxiety or psychiatric disorder			
Pregnancy (when large doses are required)			
Glaucoma			
Unstable diabetes mellitus			
Hypersensitivity to sulfites		Epinephrine allergy	

With respect to drug interactions, caution must be used when administering epinephrine-based anesthetics in those who are taking antidepressants and/or beta-blockers.^{5,6} Epinephrine and propranolol together can result in a life-threatening systemic reaction.^{14,124} The injection of epinephrine in a patient receiving propranolol results in unopposed alpha-1 vasoconstriction activity.¹⁴ This can result in a marked hypertension followed by reflex bradycardia, which ultimately can lead to a cardiac or neurologic event.^{6,14,124} This reaction has been reported to occur with only 8-mL lidocaine with 1:200,000 of epinephrine (a very low systemic dose of epinephrine), in a patient taking Inderal, 60 mg daily.¹²⁴ For smaller dermatologic procedures such as biopsies, this interaction may not be as clinically important.¹⁴ For larger skin surgeries requiring more local anesthesia, it may be advisable to have patients adjust or temporarily wean off their beta-blocker as directed by their primary care physician before the scheduled procedure.¹⁴

Allergic reactions

Types 1 and 4 hypersensitivity reactions to topical and local anesthetics have been reported but are rare.^{6,28} Type 1 reactions are IgE mediated, immediate, and can lead to anaphylaxis.⁵ Ester-derived anesthetics are more often associated with allergic reactions than amide anesthetics.⁵ There is no cross

reactivity between ester and amide reactions.⁶ Ester anesthetics are metabolized to PABA, a common allergen that cross reacts with thiazides, sulfonyleureas, and hair dyes containing paraphenylenediamine (PPD).^{6,111} Amide-induced allergic reactions are rare and are likely due to methylparabens found in the preservative.^{5,108,111} When a patient has a documented history of procaine or PABA sensitivity, the use of preservative-free lidocaine is recommended.^{6,111} If a mild reaction is noted, it can be managed with antihistamines and topical corticosteroids.^{5,6} When anaphylaxis is suspected, it should be quickly addressed by activating EMS and administering 0.3 to 0.5 mg of epinephrine subcutaneously along with basic life-support measures.^{6,125}

There are no specific recommendations to test for allergic reactions to local anesthetics.^{5,111} Some authors advise the use of patch tests or intradermal testing with preservative free lidocaine in high-risk patients.^{6,111} Another option is to avoid local anesthetic agents entirely. Nontraditional anesthetics which have been shown to be effective include ice, normal saline, diphenhydramine 1%, bacteriostatic saline,²⁸ intradermal tramadol, and metoclopramide.^{5,126,127} Shave biopsy sites may be easily anesthetized with normal saline or liquid nitrogen. Diphenhydramine is more sedating^{5,6} and painful¹²⁶ than lidocaine and can rarely lead to skin necrosis.¹²⁷ Intradermal tramadol can induce local-site skin reactions.^{6,128,129} When faced with the dilemma of what is the best anesthetic agent to use in a high-risk patient, it is probably the best to consult with an allergist.^{5,6} In this way, one can most accurately assess the degree and nature of the allergy, attempt to desensitize the patient to that allergen, and identify the safest anesthetic approach for the patient.

Methemoglobinemia

Methemoglobinemia is the process in which hemoglobin is oxidized to a non-oxygen-carrying state instead of oxygen-carrying reduced state.^{5,6} Benzocaine and prilocaine are most often associated with methemoglobinemia.⁶ Infants and children are more susceptible to hemoglobin oxidation given that they may have more susceptible hemoglobin

F, have less reductive enzymes, and a lower body weight.^{5,6,112} Other risk factors for methemoglobinemia include glucose 6-phosphate dehydrogenase deficiency, methemoglobin reductase deficiency, and use of medications such as antimalarials and sulfonamides (Table 12-14).^{5,130} Rare cases have also been reported with EMLA cream.^{5,112}

Table 12-14. Risk Factors Associated with Methemoglobinemia

■ G6PD deficiency
■ Methemoglobin reductase deficiency
■ Infants and children
■ Less reductive enzymes
■ Hemoglobin F susceptibility
■ Lower weight
■ Simultaneous medication ingestion
■ Antimalarials
■ Dapsone
■ Nitrates
■ Phenobarbital
■ Sulfonamides

Table 12-15. Recommended Pediatric Doses for EMLA Cream^a

Age	Weight	Max Dose (g)	Max Application Area (cm ²)	Application Time (hours)
0–3 months	<5 kg	1	10	1
3–12 months	5–10 kg	2	20	4
1–6 years	10–20 kg	10	100	4
7–12 years	20 kg	20	200	4

^aFor applying to intact skin only. Caution must be taken if applying to injured or inflamed skin as EMLA absorption can vary in these areas.

When evaluating and treating methemoglobinemia, it is important to recognize that conventional pulse oximetry is unreliable.^{5,6} The presence of cyanosis without the presence of cardiorespiratory disease is a strong clinical indicator.⁶ Actual blood levels of methemoglobin or arterial blood gases are required for accurate diagnosis.⁶ Methemoglobin levels below 30% can be managed with observation, oxygen, and the elimination of further local anesthetic delivery.^{5,6,125} Higher methemoglobin levels may require IV methylene blue administered at a 1- to 2-mg/kg dose.^{5,6} In those with G6PD

deficiency, methylene blue is contraindicated, though ascorbic acid and/or hemodialysis can be utilized.^{5,6,125,130}

Children

The recommended doses for lidocaine without epinephrine in children over 3 years of age should not exceed 1.5 to 2.0 mg/kg, and with epinephrine 3.0 to 4.5 mg/kg.^{6,14} The use of preservative-free anesthetic is preferred in neonates with jaundice.³⁸ This is due to the intrinsic bilirubin displacement properties of parabens found within preservative-containing anesthetics.

Topical anesthetics can induce toxicity in children, and care must be taken when using these agents.^{5,56} The recommended pediatric doses for EMLA cream can be found in Table 12-15.^{5,53}

Pregnancy considerations

Local anesthetics are generally considered safe during pregnancy, despite the fact that they can cross the placenta via passive diffusion.⁶ Studies have demonstrated safety with first-trimester lidocaine use with no adverse maternal or teratogenic effects.¹²³ Lidocaine, etidocaine, and prilocaine are categorized as Category B drugs.⁶ Bupivacaine and mepivacaine are classified as Category C because of their potential to induce fetal bradycardia.^{6,123} Infant toxicity has also been reported in lactating mothers treated with large volumes of local anesthesia agents.¹²³

PREOPERATIVE, INTRAOPERATIVE, AND POSTOPERATIVE CONSIDERATIONS

Preoperative considerations

Preoperative anxiolytics and pain medications are sometimes used prior to longer dermatologic surgery procedures such as liposuction, laser resurfacing, and/or large flap repairs.⁶ Adjuvant perioperative medications require discussion with the patient before the actual procedure is

performed.^{6,131} The dermatologist must ensure that the patient has a ride to and from the office, review with the patient the need for continuous monitoring, and discuss the potential adverse effects of using anxiolytics and narcotics. The latter risks including somnolence, nausea, amnesia, and drug-induced allergic reactions.

One preoperative cocktail utilizes triazolam 0.25 mg, promethazine 25 to 50 mg, and hydrocodone with acetaminophen (Table 12-16). The patient's history and physical examination, photographs, and informed consents are taken care of ahead of time in a separate preoperative visit. On the day of surgery, the patient is brought into the operative suite where their vital signs and O₂ saturation measurements are taken. If the patient vitals are stable, an anxiolytic, antiemetic, analgesic, or topical anesthetic is given. Within 30 minutes, the patient is usually comfortable to a point where nerve blocks or tumescent anesthesia can be administered.

Table 12-16. Oral Preoperative Regimen Given Prior to Major Skin Surgery

Triazolam 0.25–0.5 mg
Promethazine 25–50 mg
Hydrocodone bitartrate 7.5 mg with acetaminophen 325 mg
Administered 30 minutes before procedure at office if BP and pulse are stable (systemic blood pressure 90–160 mmHg, pulse >50 bpm)

Patients should be instructed preoperatively to have someone drive them to and from the office.

If extensive sedation is required, intravenous midazolam, propofol, and/or fentanyl can be used (Table 12-17).^{6,131,132} In these instances, an anesthesia provider dedicated to patient monitoring should be in place.¹³¹ It is recommended that this provider be a different person than the dermatologic surgeon. A transfer agreement to a nearby hospital should be available and ready to execute in case of an unforeseen emergency. Surgeons and their staff should be well versed in ACLS algorithms,¹³¹ and if any patient complication occurs, for example, drop in blood pressure, low oxygen saturation, arrhythmia, or patient unresponsiveness, the procedure should be

immediately stopped, EMS activation initiated, and ACLS protocols followed.

Table 12-17. Example of an IV Sedation Protocola

Establish an IV line and evaluate the patient with ECG, BP cuff, and O ₂ saturation monitor	
O ₂ administration with a nasal cannula—keep O ₂ Sat >90%	IV infusion of normal saline or lactated Ringer's solution
Midazolam—0.5–2 mg administered over 1–2 minutes, can use up to 0.6 mg/kg in resistant cases, but such doses may prolong recovery, reversible with flumazenil	
Fentanyl 1–2 µg/kg—100–200 mcg bolus followed by 1–2 µg/kg/hr by continuous infusion	
Initiate sedation slowly with a continuous infusion technique to desired level of conscious sedation as measured by the Ramsey scale	
Consider propofol infusion at 25–50 µg/kg/min	
Look for signs of clinical endpoints such as slurred speech, nystagmus. The dosages of the above-mentioned medications may need to be adjusted according to patient's health, age, and desired level of sedation.	

^aA separate provider should administer the anesthesia and transfer agreement should be in place with a nearby hospital in case of an emergency.
Modified with permission from Abeles G, Warmuth IP, Sequeira M, et al: The use of conscious sedation for outpatient dermatologic surgical procedures, *Dermatol Surg.* 2000 Feb;26(2):121–126.

Intraoperative considerations

For short dermatologic procedures, buffered lidocaine 1% with 1:100,000 epinephrine can be used as a solitary anesthetic. With longer cases, such as Mohs surgery and four-lid blepharoplasty surgery, the addition of bupivacaine or etidocaine can be added to maximize the anesthetic duration.^{5,6} For longer surgeries, buffered lidocaine is administered first in order to provide more comfort for the patient prior to injecting bupivacaine, which is a much more painful and slower-acting anesthetic. Anesthetic is drawn up using an 18-gauge syringe and subsequently injected into the skin using a 30-gauge needle.

Cold compresses prior to injection can also serve to alleviate patient discomfort.¹³³ Hemostasis can be optimized by waiting for 5 to 10 minutes post-injection.⁵ For infected sites, larger volumes of local anesthetic may be required because they work less effectively in bacteria- laden acidic environments.⁵

For procedures requiring multiple injections, it is useful to advance the needle in an area that has been previously anesthetized.⁶ Puncture number can be reduced by using longer needles or employing cannulas. Ring blocks are a great consideration for cyst removal, incision and drainage procedures, lipoma removal, and scalp and ear procedures.^{5,6}

For surgeries involving the face, such as laser resurfacing, or the hand, foot, and digits, nerve blocks are ideal.^{5,6,92} They require less anesthetic,

create minimal tissue distortion,^{5,6} and are often less painful. The disadvantages of nerve blocks are that they take time to complete⁵ and do not provide hemostasis.⁶

For larger procedures requiring higher anesthetic volumes, tumescent anesthesia should be utilized, which allows for higher doses of lidocaine to be delivered with minimal toxicity and increased effectiveness.⁵

Concentrations used will vary based on the area and procedure type.⁵ Facelifts and neck liposuction procedures usually require a higher concentration of anesthetic solution, for example, lidocaine 0.3%, whereas abdominal liposuction cases can be effectively performed using much lower concentrations, for example, lidocaine 0.05% to 0.1%.

Topical anesthesia use is especially effective in mucosal areas or prior to pediatric procedures such as wart or molluscum removal.⁵ They can be applied over a treatment site “like cream cheese on a bagel” or under occlusion in limited areas. The removal of skin tags, hemangiomas, and incision and drainage procedures are less painful with topical anesthetic formulations. Combined approaches using topical anesthetics with nerve blocks are a great way to help laser resurfacing and dermabrasion patients achieve optimal comfort without the need for general anesthesia.

Postoperative considerations

Postoperatively, patients have varied pain and anxiolytic needs (Table 12-18).⁶ For standard dermatologic procedures, most individuals do not require systemic narcotics. If patients do experience postoperative pain, cool compresses combined with ibuprofen and acetaminophen can be employed.⁶ One common approach for minor postoperative pain is to have patients alternate acetaminophen with ibuprofen every 4 hours. For extensive skin surgery procedures, patients may require postoperative narcotics such as acetaminophen with codeine and/or hydrocodone.⁶ Pain control is important for both patient and surgeon alike; analgesics help to minimize postoperative bleeding risks that occur with blood pressure spikes that occur when patients are experiencing pain from their surgery.

Table 12-18. Other Postoperative Considerations

- Personally calling the patient to ensure a smooth postoperative course and alleviate any concerns that they may have.
 - Alternate acetaminophen 500–1000 mg with ibuprofen 600 mg every 4 hours.
 - Cool compresses over surgery areas for 5–10 minutes every hour as tolerated.
 - For laser resurfacing cases, mix three parts petrolatum with one part topical anesthetic and to apply this to a completely treated area while the nerve block is still working. Have patients reapply this mixture every 2–3 hours for the first 24 hours.
 - Injecting an additional amount of bupivacaine or tumescent anesthetic solution at the end of the surgery. This will help the patient gain some added pain relief as they wait for their oral pain medication to take effect.
-

For postoperative laser resurfacing cases, mix three parts petrolatum with one part topical anesthetic and apply this to a completely treated area, while the nerve block is still working, for example, complete the laser procedure on one-half of the face and immediately apply the dilute topical anesthetic agent. With this approach, patients leave the office very comfortable. They are advised to reapply this numbing mixture every 2 to 3 hours for the first 24 hours. After this period, patient discomfort is minimal and they usually only complain of warmth and swelling which can be easily managed with cool compresses and oral ibuprofen.

The third postoperative consideration to optimize patient comfort is to inject an additional amount of bupivacaine or tumescent anesthetic solution postoperatively.^{6,80,81} This will help the patient gain some added pain relief while they wait for their oral pain medication to take effect.

SUMMARY

Local anesthesia is a vital part of dermatologic surgery. The correct use and understanding of these agents have helped dermatology patients undergo their procedures in a safe and effective manner without the risks of general anesthesia. Knowledge of how and why we use these medications is of

extreme importance to the dermatologic surgeon. As new scientific breakthroughs occur in the area of local anesthesia and delivery systems, the fruits of this knowledge will hopefully help our specialty advance for the betterment of our patients.

CHAPTER 13 Suturing Techniques

Jonathan Kantor

SUMMARY

- While most day-to-day procedures demand only a few suturing techniques, recent evidence has suggested that choice of technique has the potential to impact long-term outcomes.
- Suturing techniques can be dichotomized as buried versus transepidermal techniques, though the use of percutaneous approaches may make this distinction unclear.

- While the dermatologic surgeon does not need to incorporate a vast array of techniques into daily practice, precise placement of sutures coupled with an appreciation of the subtle variations in individual patients that may benefit from particular niche techniques is very helpful and may result in improved surgical outcomes.

Beginner Pearls

- Deep suture techniques, such as the buried vertical mattress or set-back dermal suture, are fundamental techniques for all wound closures, as they lead to wound eversion, wound-edge approximation, and shift tension to the dermis.
- Fascial plication sutures are very useful to reduce dead space and reduce tension, and serve to shift tension even deeper, ultimately leading to a possibly improved outcome.

Expert Pearls

- When suturing a tight location, such as the scalp or lower leg, either percutaneous approaches or a buried horizontal mattress suture may be used for the deeper layer of sutures.

- With meticulous suture placement, no transepidermal sutures are needed for many closures, as the deep sutures lead to both tension reduction and wound-edge approximation.

Don't Forget!

- When working on the back, use thicker suture such as a 2-0 absorbable suture with a large needle.
- To reduce the risk of suture material spitting, consider using set-back sutures that leave no suture material at the incised wound edge.

Pitfalls and Cautions

- Pulley variations may be useful for wounds under significant tension, but always using a pulley approach may needlessly increase the amount of suture material left in the wound, leading to an increased risk of foreign body reactions and suture material spitting.
- Fascial plication sutures may increase the risk of pain or infection; if pain after suture placement persists for more than 30 seconds, the suture should be removed.

Patient Education Points

- The dramatic eversion seen after dermatologic surgery should be explained to patients ahead of time and reviewed repeatedly.
- Using the analogy of a subcutaneous splint (or cast) may be helpful when explaining that the goal is to reduce tension temporarily but that the eversion will not persist.

Billing Pearls

- An intermediate or complex repair code is predicated on the wound being closed in a layered fashion.
- Fascial plication followed by dermal sutures would be considered a layered closure for these purposes.

CHAPTER 13 Suturing Techniques

INTRODUCTION

Suturing techniques have seen a renaissance over the past decades, as dermatologic surgeons have increasingly appreciated the impact that precisely placed sutures have on surgical outcomes. The rise of evidence-based medicine has led to a boon in suture technique development, as surgeons have become more willing to consider changing the fundamental techniques that were adopted during training in an effort to provide even better patient outcomes.

Even the best-designed flaps can be undone by less- than-optimal suturing techniques and tissue handling. While most day-to-day procedures demand only a very few suturing techniques, recent evidence has suggested that choice of technique has the potential to impact long-term outcomes.¹

Suturing techniques can be dichotomized as buried versus transepidermal techniques, though the use of percutaneous approaches, discussed in detail below, may make this distinction sometimes unclear. In general, the buried techniques are those that do not require suture removal, while the transepidermal approaches necessitate suture removal unless rapidly absorbing suture materials are used.

BURIED SUTURE TECHNIQUES

The buried vertical mattress suture

This technique is a common approach widely utilized by dermatologists and plastic surgeons (Figs. 13-1 through 13-3).²

Figure 13-1. The needle is inserted through the underside of the dermis and moves upwards and outwards in the dermis before returning to exit at the incised wound edge.

Figure 13-2. The needle is then inserted through the incised wound edge before moving upwards and outwards away from the wound edge and exiting in the deeper dermis.

Figure 13-3. Lateral view of the buried vertical mattress suture highlighting the heart-shaped path the suture material takes through the dermis.

Buried Horizontal Mattress Suture Step-by-Step

- a. The wound edge is reflected back using surgical forceps or hooks. Adequate visualization of the underside of the dermis is desirable.
- b. While reflecting back the dermis, the suture needle is inserted into the undersurface of the dermis parallel to the surface of the skin just lateral to the incised wound edge.
- c. The first bite is executed by placing gentle pressure on the needle so that it enters the papillary dermis and the relaxing pressure to permit the needle to exit on the undersurface of the dermis.
- d. Keeping the loose end of suture between the surgeon and the patient, the dermis on the side of the first bite is released. The tissue on the opposite edge is then reflected back in a similar fashion as on the first side.
- e. The second and final bite is executed by inserting the needle into the undersurface of the dermis on the contralateral side, with a backhand technique if desired, and completing a mirror-image loop, so that the needle exits directly across from its original entry point on the contralateral side.
- f. The suture material is then tied utilizing an instrument tie.

It requires some practice to master, though once mastered it is straightforward to execute. The first bite may also be finessed by first reflecting the wound edge back sharply during needle insertion and then returning the edge medially after the apex has been reached. This approach helps to lead the needle in the correct course without an exaggerated change in direction with the needle driver.

When suturing, both the obviously active element (the needle and needle driver, held by the dominant hand) and the ostensibly passive element (the skin, held by forceps or a skin hook) have the potential to move in three dimensions. Thus changing the way the needle moves through the skin can be accomplished by either adjusting the way the needle is moved through the skin with the dominant hand, adjusting how the skin is held or manipulated by the other hand, or a combination of the two. With experience, a combination is often more effective at affecting the vertical mattress suture in an elegant and efficient fashion.

The apex of the needle should be in the papillary dermis; if the needle courses too superficially, dimpling may occur. This technique, if executed appropriately, leads to both excellent wound eversion and outstanding wound-edge approximation.

The set-back dermal suture

This approach is frequently used in areas under significant tension, and as an alternative to the buried vertical mattress as a standard buried technique.³ Since it is easier to place than a buried vertical mattress suture, this technique may be used by budding surgeons, medical students, and residents as the workhorse technique for deep tension-relieving sutures (Figs. 13-4 through 13-6).

Figure 13-4. The needle is inserted through the underside of the dermis, exiting again through the underside of the dermis set back from the wound edge.

Figure 13-5. This is repeated on the contralateral wound edge.

Figure 13-6. Cross-sectional view demonstrating the path of the suture material through the dermis and the effect on wound eversion.

The Set-back Dermal Suture Step-by-Step

- a. The wound edge is reflected back using surgical forceps or hooks. Adequate visualization of the underside of the dermis is required.
- b. While reflecting back the dermis, the suture needle is inserted at 90 degrees into the underside of the dermis 2 to 6 mm distant from the incised wound edge.
- c. The first bite is executed by traversing the dermis following the curvature of the needle and allowing the needle to exit closer to the incised wound edge. Care should be taken to remain in the dermis to minimize the risk of epidermal dimpling. The needle does not, however, exit through the incised wound edge, but rather 1 to 4 mm distant from the incised edge. The size of this first bite is based on the size of the needle, the thickness of the dermis, and the need for and tolerance of eversion.
- d. Keeping the loose end of suture between the surgeon and the patient, the dermis on the side of the first bite is released. The tissue on the opposite edge is then reflected back in a similar fashion as on the first side, assuring complete visualization of the underside of the dermis.

- e. The second and final bite is executed by inserting the needle into the underside of the dermis 1 to 6 mm distant from the incised wound edge. Again, this bite should be executed by following the curvature of the needle and avoiding catching the undersurface of the epidermis that could result in epidermal dimpling. It then exits further distal to the wound edge, approximately 2 to 6 mm distant from the wound edge. This should mirror the first bite taken on the contralateral side of the wound.
- f. The suture material is then tied utilizing an instrument tie.

This technique was compared with the buried vertical mattress suture in a randomized trial and was found to be superior to in terms of eversion and cosmetic outcomes based on both physician and patient assessments.¹

One of the chief advantages of this technique is its ease of execution; since the suture follows the arc of the needle on the undersurface of the dermis, there is no need to change planes, affect a heart-shaped suture placement, or guarantee that the suture exit point is precisely at the inside edge of the lower dermis, as may be needed with the buried vertical mattress suture.

Accurate suture placement is predicated on having a sufficiently undermined plane, since the entire suture loop lays on the undersurface of the dermis. Therefore, broad undermining is a prerequisite for utilizing this technique, since the first throw of the needle begins 2 to 6 mm distant from the incised wound edge.

This technique may also be used to minimize dead space when excising a space-occupying lesion such as a cyst or lipoma. In this event, taking the first bite set-back even further from the incised wound edge will translate into a larger ridge and will simultaneously minimize the laxity in the central portion of the wound as the dermis is pulled taught so that potential dead space is converted to a hyper-everted wound ridge which will absorb with time.

Patients should be cautioned that they might develop a significant ridge in the immediate postoperative period. Depending on the suture material used and the density of the sutures, this ridge may last from weeks to months. Explaining that the technique is akin to placing a subcutaneous splint may help the patient develop reasonable and realistic expectations and reduce anxiety regarding the immediate postoperative appearance of the wound.⁴

A possible complication of hypereversion and an overly broad bite is that the raised ridge may be too large or bulky to be supported by the deep sutures.⁵ In this event, the wound edges may paradoxically collapse centrally leading to the appearance of a dramatically raised ridge with a central valley approximately 1 week postoperatively. As the sutures absorb over time, this will yield a depressed or inverted scar line. This can generally be avoided by not setting back the sutures more than a few millimeters from the wound edge and by placing a sufficient number of sutures so that the body of the ridge may be easily supported.

Suspension suture

This is a niche technique designed to fix one or both edges of a defect to a deeper structure. This approach has also been referred to as a pexing suture or tacking suture, and is utilized typically in several situations. First, when repairing a defect that crosses a natural sulcus, it is important to tack down the skin overlying the sulcus so that the natural depression is not blunted, or bridged, by the repair. Second, it is used when working near cosmetic subunit boundaries and free margins, to avoid functional challenges such as ectropion and eclabium, as well as cosmetic distortion of sensitive areas such as the lip and eyebrows. It is also useful in order to fix a flap in place and minimize tension on the distal portion of the flap. Finally, this approach may also be used to prevent nasal valve collapse in the appropriate setting (Fig. 13-7).

Figure 13-7. Overview of the suspension suture technique.

Suspension Suture Step-by-Step

- a. First, the surgeon determines the desired location for fixing the suspension suture, as discussed below. The wound edge is reflected back using surgical forceps or hooks, and adequate visualization of the underside of the dermis is desirable.
- b. While reflecting back the dermis, the suture needle is inserted at 90 degrees into the underside of the dermis 2 to 6 mm distant from the incised wound edge.
- c. The first bite is executed by traversing the dermis following the curvature of the needle and allowing the needle to exit closer to the incised wound edge. This will minimize the risk of vascular compromise. Care should be taken to remain in the dermis to minimize the risk of epidermal dimpling. The needle does not, however, exit through the incised wound edge, but rather 1 to 4 mm distant from the incised edge, or, in select cases, potentially further back from the wound edge.
- d. The flap of skin may be gently pulled by the suture material so that the location of the first bite directly overlies the planned fixation point. This permits the surgeon to double-check the final position of the suspension suture. The needle is then blindly inserted through the fat and deeper structures until bone is reached. A 3-mm bite of periosteum is then taken, and the needle is brought back up through the soft tissues into the open center of the wound.
- e. The suture material is then tied utilizing an instrument tie. Hand-tying may be utilized as well, which may be useful if the depth of the defect is significant.

This technique is very useful when working around the eyelids and lips, though its use demands familiarity with the underlying anatomy so that no sensitive deeper structures are injured or entrapped during the blind placement of the deep anchoring suture. The deep suture should also be placed parallel to the underlying vascular plexus to similarly mitigate this risk.

Placement is based on several considerations, including the degree of tension across the advanced tissue, the presence of a bony prominence, which can be used easily for suspension purposes, and the absence of underlying nerves, which could inadvertently become strangulated by the anchoring suture.

Pulling on the suture once it is anchored to the periosteum may help assure the surgeon that the suture is indeed tacked down to an immobile surface.

A three-point variation of this approach is possible as well, which allows wound-edge approximation and a tacking effect to occur all with one suture placement. This is accomplished by first placing either a buried vertical mattress or set-back dermal suture at the two wound edges and then taking a bite of the underlying periosteum prior to tying the knot. The suture material thus fixes the wound edges together as well as to the underlying anchoring point. This approach, however, may result in suboptimal wound-edge eversion and places additional stress on the suture material, increasing the risk of scar spread. Moreover, it is only appropriate if the anchor target lies in the approximate midpoint of the defect, since it recreates a natural sulcus but does not permit differential pull from one side of the defect.

This technique may also be used as an alternative to cartilage grafting when reconstructing the nose. Loss of alar cartilage may lead to nasal valve collapse, which traditionally was addressed by placing an auricular cartilage graft along the reconstructed alar rim in order to maintain valve patency. A simple and elegant alternative places a suture in the ala and fixes it to a point superolaterally in the maxillary periosteum, permitting the nasal valve to remain open and potentially obviating the need for a cartilage graft. Since the underside of the dermis is tacked to periosteum, this technique may result in an area of depression at the site of suspension suture placement.

Buried horizontal mattress suture

This is a niche technique, useful when closing narrow wounds or those where there is limited space to insert the needle driver, and when placing a buried suture is desirable. It may be employed in a variety of locations, including the scalp, ears, and lower leg (Figs. 13-8 and 13-9).

Figure 13-8. The needle is inserted through the dermis running parallel to the incised wound edge.

Figure 13-9. This procedure is then reversed on the contralateral wound edge.

Buried Vertical Mattress Suture Step-by-Step

- a. The wound edge is reflected back using surgical forceps or hooks. Adequate visualization of the underside of the dermis is desirable.
- b. While reflecting back the dermis, the suture needle is inserted at 90 degrees into the underside of the dermis 4 mm distant from the incised wound edge.

- c. The first bite is executed by following the needle initially at 90 degrees to the underside of the dermis and then, critically, changing the direction by twisting the needle driver so that the needle exits in the incised wound edge. This allows the apex of the bite to remain in the papillary dermis while the needle exits in the incised wound edge at the level of the reticular dermis.
- d. Keeping the loose end of the suture between the surgeon and the patient, the dermis on the side of the first bite is released. The tissue on the opposite edge is then reflected back in a similar fashion as on the first side.
- e. The second and final bite is executed by inserting the needle into the incised wound edge at the level of the reticular dermis. It then angles upwards and laterally so that the apex of the needle is at the level of the papillary dermis. This should mirror the first bite taken on the contralateral side of the wound.
- f. The suture material is then tied utilizing an instrument tie.

This technique is useful for narrow or shallow wounds, such as those on the scalp and shins.⁶ It may also be used when adding an additional buried suture in an otherwise largely closed wound, where there is insufficient space to insert a vertically oriented buried suture in the narrow space between two other already-placed sutures.

The needle driver may also be held like a pencil, and the needle may then be rotated through the dermis while reflecting back with the forceps to permit easy visualization.

Wound-edge necrosis has been raised as a potential risk of horizontally oriented suture placement, but in practice, this is only encountered very rarely and as a complication of tightly placed traditional horizontal mattress sutures, rather than with the buried equivalent. This is likely due to a constrictive effect on the incised wound edge, which is not typically seen with buried sutures.

Fascial plication suture

This technique is designed for wounds under marked tension, especially those on the back and shoulders. It can also be used for facial repairs, where

grasping the superficial musculoaponeurotic system (SMAS) with this deep suture technique leads to a dramatic reduction in wound size. It is a deep technique, permitting the tension of wound closure to shift from the dermis to the fascia, and concomitantly creating a lower-tension closure. In addition to tension reduction, this approach also leads to an increase in the apparent length-to-width ratio of a fusiform closure and improved dead-space minimization (Fig. 13-10).

Figure 13-10. Overview of the fascial plication suture technique. Note that the fascial bites may also be taken parallel to the incised wound edges.

Fascial Plication Suture Step-by-Step

- a. The wound edges are reflected back to permit visualization of the deep bed of the wound. In deep excisions, such as those performed for melanoma or large cysts, the muscle fascia may be directly visible. Otherwise, visualizing the subcutaneous fat is appropriate as well.

- b. The suture needle is inserted at 90 degrees through the deep fat 2 to 4 mm medial to the lateral undermined edge of the wound.
- c. The first bite is executed by entering the fascia and following the curvature of the needle. The suture material may be gently pulled to test that a successful bite of fascia has been taken.
- d. Keeping the loose end of suture between the surgeon and the patient, attention is then shifted to the opposite side of the wound. The second bite is executed by repeating the procedure on the contralateral side.
- e. The suture material is then tied utilizing an instrument tie. Hand-tying may be utilized as well, particularly if the wound is deep and the instruments cannot be easily inserted to complete the tie.

This technique is very useful for wounds under marked tension, especially for large defects on the back and shoulders.^{7,8} Even a deep, gaping wound can be converted into a manageable fusiform defect with a single well-placed fascial plication suture. It can, therefore, be conceptualized as an alternative to pulley sutures that affords both a decrease in tension across the wound surface (by shifting tension from the dermis to the fascia) and an increase in the length-to-width ratio of the ellipse.

Indeed, this approach often leads to a more fusiform defect, even when an oval-shaped excision has been performed. Therefore, it may be useful when attempting to keep a defect as short as possible without dog-ear formation. In cases where this approach is anticipated, it may be worthwhile to create a defect with a length-to-width ratio of less than 3 to 1, as is traditionally employed, as that may be sufficient to lead to a tapered ellipse.

Fascial plication sutures need not be used for all linear closures. This technique is most appropriate for areas under significant tension, or large excisions where minimizing the postoperative wound length is desirable. On the face, recruiting the SMAS may be very helpful. When designing the closure of a round defect, the fascial plication suture should be placed prior to removing the dog ears. The risks of fascial plication sutures include possible pain, a theoretically increased infection risk (since the fascial envelope has been pierced by suture), and a theoretical risk of vascular compromise through inadvertent pressure-induced ligation of perforating vessels. In practice, these complications are infrequent, though patients may experience transient pain during needle entry and immediately after the

fascial plication suture is tied. If pain persists for more than 5 minutes, the suture should be removed.

Buried purse-string suture

This technique is designed to either shrink the size of a defect or obviate it entirely, depending on the degree of tension and the size of the defect. The purse-string effect tends to lead to a slight puckering in the surrounding skin, a feature that may be acceptable (and will likely resolve with time) on areas such as the forearms and back, but is less desirable in cosmetically sensitive locations such as the face. The running nature of the technique means that compromise at any point in the course of suture placement may result in wound dehiscence, though for this reason a larger gauge suture material is generally utilized (Fig. 13-11).

Figure 13-11. Overview of the buried purse-string suture technique.

Buried Purse-string Suture Step-by-Step

- a. The wound edge at the far end of the round- or oval-shaped wound, parallel to the incision line, is reflected back.

- b. With the tail of the suture material resting between the surgeon and the far end of the wound, the needle is inserted into the underside of the dermis on the far edge of the wound with a trajectory running parallel to the incision. In general, this entry point in the dermis should be approximately 3 to 6 mm set back from the epidermal edge, depending on the thickness of the dermis and the anticipated degree of tension across the closure. The needle, and therefore the suture, should pass through the deep dermis at a uniform depth. Bite size is dependent on the needle size; though in order to minimize the risk of necrosis, it may be prudent to restrict the size of each bite. The needle should exit the dermis at a point equidistant from the cut edge from where it entered.
- c. The needle is then grasped with the surgical pickups and simultaneously released by the hand holding the needle driver. As the needle is freed from the tissue with the pickups, the needle is grasped again by the needle driver in an appropriate position to repeat the above step to the left of the previously placed suture.
- d. A small amount of suture material is pulled through and the needle is inserted into the dermis to the left of the previously placed suture, and the same movement is repeated.
- e. The same technique is repeated moving stepwise around the entire wound until the needle exits close to the original entry point at the far end of the wound.
- f. Once the desired number of throws has been placed, the suture material is then pulled taught, leading to complete or partial closure of the wound, and tied utilizing an instrument tie.

This technique is designed as an efficient method of wound area reduction. In many cases, placing a purse-string suture can affect complete wound closure and it therefore represents an alternative to a layered repair of a fusiform incision.

It has been suggested that some defects on the back and extremities, particularly in elderly patients with loose skin, are better closed with a purse-string approach than with a traditional linear closure, since linear closures often heal with a residual scar and require a significantly longer excision line, while the puckering that may be present immediately postoperatively with purse-string closures is likely to resolve with time.⁹⁻¹⁴

That said, in the right hand, linear closures on the trunk and extremities often heal with subtle scarring, even when wounds are closed under tension.

On a pragmatic level, this approach is generally utilized when either a patient is unwilling to undergo a traditional linear closure or when their comorbidities make the additional length of the incision for a linear closure an unrealistic option.

As with linear running dermal techniques, this technique may be used as a modified winch or pulley suture, since the multiple loops help to minimize the tension across any one loop and permit closure of wounds under marked tension. Because each throw is not tied off, it is important to adequately secure the knot.

As with other running dermal techniques, this approach leaves a fair amount of absorbable suture material in the dermis. Therefore, foreign-body reactions, suture abscess formation, and infection are possibilities. That said, since the entire suture line is secured with a single knot, and since most of the bulk of any suture line is in the knots, rather than the lengths of suture material between knots, this technique may be less susceptible to suture abscess or suture spitting than others.

The pucker effect of this closure resolves rapidly in atrophic skin, though it can persist in other areas; patients should realize that some degree of residual puckering toward the center of the wound is to be expected. Additionally, this technique may be used to help recreate the nipple–areola complex if full reconstruction is not desired and the nipple is lost to a local tumor.

Since the entire closure is held by a single knot, this approach may be associated with a higher rate of wound dehiscence, as knot failure in the suture material at any point leads to an immediate loss of tension on the closure. Given the concern regarding knot breakage, it may be helpful to attempt to better secure the knot. This may be done by paying particularly close attention to knot tying, tying an extra full knot, adding extra throws, or leaving a longer tail than would traditionally be executed.

A recent study has suggested, however, that the postoperative cosmesis of a purse-string closure is no better than a wound allowed to heal with secondary intention healing.¹⁵

VARIATIONS

Pulley variations

Pulley (or double) variations are available for most buried suturing techniques. Typically, pulley variations confer two central advantages: they permit the closure of high-tension wounds, where the mechanics of a pulley allow straightforward wound-edge approximation, and they typically lock in place immediately, obviating the need for an assistant. Frequently used approaches include the pulley buried vertical mattress suture (Figs. 13-12 through 13-15)¹⁶⁻¹⁹ and the pulley set-back suture (Figs. 13-16 through 13-19).²⁰

Figure 13-12. The pulley buried vertical mattress suture. The needle is inserted through the dermis, angling upwards and outwards before exiting at the incised wound edge.

Figure 13-13. The needle is then inserted through the incised wound edge on the contralateral side, again moving superolaterally before exiting deep.

Figure 13-14. Keeping the tail of the suture deep to the suture throws and toward the surgeon, the first step is then repeated, with the needle entering deep and exiting at the incised wound edge.

Figure 13-15. Again with the tail deep, the needle is inserted through the incised wound edge on the contralateral side.

Figure 13-16. The pulley set-back dermal suture. The needle is inserted through the underside of the dermis, exiting the underside of the dermis closer to the incised wound edge but still set back from the incised wound edge.

Figure 13-17. The needle is then inserted through the underside of the dermis on the contralateral wound edge, exiting further away from the incised wound edge on the undersurface of the dermis.

Figure 13-18. With the loose end of the suture material deep to the active sutures and resting between the surgeon and the needle driver, the needle is then reinserted through the undersurface of the dermis.

Figure 13-19. The procedure is again repeated on the contralateral wound edge.

Running variations

Running variations of buried sutures permit rapid placement of a long row of buried sutures that are anchored by knots at either end. The speed advantage is offset, however, by the reliance on only two anchor points along an entire wound. Since buried sutures are designed to bear the tension across a wound, relying on a single anchoring suture knot at each end of the wound may be unwise, as break in suture material anywhere along the suture line (or knot compromise at either end) may result in catastrophic consequences.

Percutaneous variations

When placing sutures in narrow areas, percutaneous approaches allow the placement of buried sutures when only minimal visualization is possible. This is particularly useful on the tight skin of the scalp, and when executing narrow closures on the nose and below the knee. Approaches include the percutaneous buried vertical mattress (Fig. 13-20), the percutaneous set-back suture (Fig. 13-21), and the percutaneous horizontal mattress suture (Fig. 13-22).

Figure 13-20. The percutaneous buried vertical mattress suture.

Figure 13-21. The percutaneous set-back suture technique.

Figure 13-22. The percutaneous horizontal mattress suture technique.

TRANSEPIDERMAL SUTURE TECHNIQUES

The simple interrupted suture

This is the standard benchmark suture used for closure and epidermal approximation. It may be used alone in the context of small wounds under minimal to no tension, such as those formed by either a small punch biopsy or a traumatic laceration. It is also frequently used as a secondary layer to aid in the approximation of the epidermis when the dermis has been closed using a dermal or other deep suturing technique (Fig. 13-23).

Figure 13-23. Overview of the simple interrupted suture technique.

The Simple Interrupted Suture Step-by-Step

- The needle is inserted perpendicular to the epidermis, approximately one-half the radius of the needle distant to the wound edge. This will allow the needle to exit the wound on the contralateral side at an equal distance from the wound edge by simply following the curvature of the needle.
- With a fluid motion of the wrist, the needle is rotated through the dermis, taking the bite wider at the deep margin than at the surface, and the needle tip exits the skin on the contralateral side.
- The needle body is grasped with surgical forceps in the left hand, with care being taken to avoid grasping the needle tip, which can be easily dulled by repetitive friction against the surgical forceps. It is gently grasped and pulled upwards with the surgical forceps as the body of the needle is released from the needle driver. Alternatively, the needle may be released from the needle driver and the needle driver itself may be used to grasp the needle from the contralateral side of the wound to complete its rotation through its arc, obviating the need for surgical forceps.
- The suture material is then tied off gently, with care being taken to minimize tension across the epidermis and avoid overly constricting the

wound edges.

It is important to enter the epidermis at 90 degrees, allowing the needle to travel slightly laterally away from the wound edge before fully following the curvature of the needle when utilizing this technique. This will allow for maximal wound eversion and accurate wound-edge approximation. The final cross-sectional appearance of the needle's course should be a flask-like shape, wider at the base than at the surface.

Care should be taken to avoid skimming the needle superficially beneath the epidermis. This results from failing to enter the skin at a perpendicular angle and failing to follow the curvature of the needle. This may result in wound inversion as the tension vector of the shallow bite pulls the wound edges outwards and down.

This technique may elicit an increased risk of track marks, necrosis, and other complications when compared with techniques that do not entail suture material traversing the scar line, such as buried or subcuticular approaches. Therefore, sutures should be removed as early as possible to minimize these complications, and consideration should be given to adopting other closure techniques in the event that sutures will not be able to be removed in a timely fashion. Some studies have also demonstrated an increased rate of dehiscence when utilizing interrupted sutures alone without underlying dermal tension-relieving sutures, highlighting that this technique should be used either for wounds under minimal tension or in concert with deeper tension-relieving sutures.²¹⁻²⁶

Vertical mattress suture

This is a frequently used everting technique for closure and epidermal approximation (Fig. 13-24).

Figure 13-24. Overview of the vertical mattress suture.

This technique is generally used for its pronounced effect on wound eversion. Therefore, while it is appropriate for most skin closures, it should be avoided when either inversion is desired or when exaggerated eversion has already been accomplished with a buried suture.²⁷⁻²⁹

Vertical Mattress Suture Step-by-Step

- a. The needle is inserted perpendicular to the epidermis, approximately 6 mm distant to the wound edge.
- b. With a fluid motion of the wrist, the needle is rotated through the dermis, taking the bite wider at the deep margin than at the surface, and the needle tip exits the skin on the contralateral side. (If the needle radius is too small to complete this arc in one movement, this first step may be divided into two, with the needle first exiting between the incised wound edges and then reloaded and reinserted to exit on the contralateral side.)

- c. The needle body is grasped with surgical forceps in the left hand and pulled upwards with the surgical forceps as the body of the needle is released from the needle driver. Alternatively, the needle may be released from the needle driver and the needle driver itself may be used to grasp the needle from the contralateral side of the wound to complete its rotation through its arc, obviating the need for surgical forceps.
- d. The needle is then reloaded in a backhand fashion and inserted at 90 degrees perpendicular to the epidermis approximately 3 mm from the wound edge on the same side of the incision line as the exit point, between the exit point and the incised wound edge.
- e. The needle is rotated superficially through its arc, exiting on the contralateral side of the wound 3 mm from the incised wound edge.
- f. The suture material is then tied off gently, with care being taken to minimize tension across the epidermis and avoid overly constricting the wound edges.

As with the simple interrupted suture, care should be taken to avoid skimming the needle superficially beneath the epidermis. This may result in wound inversion as the tension vector of the shallow bite pulls the wound edges outwards and down.

Note that the second throw is placed superficial to the first, deeper far–far suture, leading to a nested placement of the suture material. This leads to both wound eversion as well as wound-edge approximation.

The Allgöwer technique involves performing a half-buried vertical mattress suture: the needle is passed from the far entrance point to the interior of the wound. A buried vertical mattress bite is then taken on the contralateral side, and the needle then passes back to the original side, entering near the incised wound edge so that one-half of the wound is closed with a standard vertical mattress suture and the other is closed with a buried vertical mattress.

This technique does not typically permit the same degree of wound-edge apposition as can be accomplished with other transepidermal sutures. In the event that deeper sutures were carefully placed, this may not be a significant drawback, since the wound edges may be well aligned from the placement of these deeper sutures. If not, or if there is a need for improved wound-edge apposition even after placing the vertical mattress suture, additional interrupted sutures may be helpful.

Horizontal mattress

This is a frequently used everting technique used for closure and epidermal approximation. This technique may also be used in the context of atrophic skin, as the broader anchoring bites may help to limit tissue tear-through that may be seen with a simple interrupted suture (Fig. 13-25).

Figure 13-25. Overview of the horizontal mattress suture.

Horizontal Mattress Step-by-Step

- The needle is inserted perpendicular to the epidermis, approximately one-half the radius of the needle distant to the wound edge. This will allow the needle to exit the wound on the contralateral side at an equal distance from the wound edge by simply following the curvature of the needle.
- With a fluid motion of the wrist, the needle is rotated through the dermis, taking the bite wider at the deep margin than at the surface, and the needle tip exits the skin on the contralateral side.
- The needle body is grasped with surgical forceps in the left hand and pulled upwards as the body of the needle is released from the needle driver. Alternatively, the needle may be released from the needle driver

and the needle driver itself may be used to grasp the needle from the contralateral side of the wound to complete its rotation through its arc, obviating the need for surgical forceps.

- d. The needle is then reloaded in a backhand fashion and inserted 90 degrees perpendicular to the epidermis proximal (relative to the surgeon) to its exit point along the length of the wound on the same side of the incision line as the exit point.
- e. The needle is rotated through its arc, exiting on the right side of the wound (relative to the surgeon) in a mirror image of steps b and c.
- f. The suture material is then tied off gently, with care being taken to minimize tension across the epidermis and avoid overly constricting the wound edges.

Since a wide bite of dermis and epidermis is included in the suture arc, it is particularly important to avoid tying the suture material too tight, as this could lead to wound-edge necrosis. Some surgeons utilize bolsters when utilizing this technique under high tension, such as when a 3-0 suture is used on the back, in an attempt to avoid track marks and reduce the risk of tissue necrosis. A wide array of materials may be used for the bolster, including gauze, dental rolls, or plastic tubing. In practice, bolsters are rarely needed with this technique as long as the bulk of the wound tension has been shifted deep using fascial or dermal buried sutures.

Tip stitch

This technique is designed to bring three ends of tissue together, and is often used in the context of a flap, where it permits the tip of tissue to be inset. This approach may be conceptualized as a half-buried horizontal mattress suture ([Fig. 13-26](#)).

Figure 13-26. Overview of the tip stitch.

Tip Stitch Step-by-Step

- The flap is brought into place using buried sutures, allowing the tip to rest with only minimal tension in its desired position.
- The needle is inserted into the distal edge of the distal nonflap section of skin at 90 degrees with a trajectory running toward the planned entry point in the tip.

- c. The needle is then grasped with the surgical pickups and simultaneously released by the hand holding the needle driver. As the needle is freed from the tissue with the pickups, the needle is grasped again by the needle driver in an appropriate position to place the next throw.
- d. The needle is inserted into the distal portion of the tip at the level of the superficial dermis, which should be the same depth at which it exited in the prior step. Keeping the needle running horizontally, parallel with the skin surface, it is rotated through the dermis of the tip, exiting on the proximal side of the tip at the same depth.
- e. The needle is then reloaded in a backhand fashion and inserted into the dermis of the proximal nontip section of skin, exiting, parallel to its initial entry point.
- f. The suture material is then gently pulled taught and tied utilizing an instrument tie. Care should be taken to minimize tension on this suture to mitigate the risk of flap tip necrosis.

The tip stitch is very useful when bringing the tip of a flap into place, and is used frequently in this situation.^{30–32} Importantly, this technique is designed to gently approximate the tissues so that the flap is properly inset in the surrounding skin. While it bears a technical resemblance to the half-buried horizontal mattress, it is important to appreciate that the tip stitch is *not* designed to work under significant tension, as tension across the suture may lead to necrosis of the delicate and lightly vascularized tip of the flap.

Flap tip necrosis is the greatest risk with this technique, since suture material traverses the dermis containing the tip's vascular supply. This risk may be mitigated by tying the suture relatively loosely so that the tip is not overly constricted when the knot is tied. Additionally, if the bites of dermis are sufficiently set back from the wound edge, a small bite comprising less than half of the dermis in the tip could be taken. This would allow blood supply to the tip even in the context of a relatively tight loop running through the distal flap.

There is sometimes a tendency for the tip to sit deeper than the surrounding tissues. This may be related to the relative upward pull on the nontip sections of skin by the transepidermal sutures.

Finally, while flap tip necrosis is a risk, studies have suggested that the tip stitch provides less vascular constriction than other options, such as placing

two vertically oriented sutures at the edges of the tip or a suture directly through the tip itself.³¹

Purse-string suture

As with its buried variant, this technique is designed to either shrink the size of a defect or obviate it entirely, depending on the degree of tension and the size of the defect (Fig. 13-27).

Figure 13-27. Overview of the purse-string suture.

Purse-string Suture Step-by-Step

- a. The wound edges are broadly undermined.
- b. With the tail of the suture material resting between the surgeon and the far end of the wound, the needle is inserted through the epidermis on the far edge of the wound with a trajectory running parallel to the incision. The entry point in the epidermis should be approximately 3 to 6 mm set-back from the epidermal edge, depending on the thickness of the dermis and the anticipated degree of tension across the closure. The needle, and

therefore the suture, should pass through the deep dermis into the undermined space at a uniform depth.

- c. The needle is then grasped with the surgical pickups and simultaneously released by the hand holding the needle driver. As the needle is freed from the tissue with the pickups, the needle is grasped again by the needle driver in an appropriate position to repeat the above step to the left of the previously placed suture.
- d. A small amount of suture material is pulled through and the needle is inserted into the dermis to the left of the previously placed suture, and the same movement is repeated.
- e. The same technique is repeated moving stepwise around the entire wound until the needle exits close to the original entry point at the far end of the wound. Once the point closest to the surgeon is reached, it may be more comfortable to shift to a backhand technique.
- f. Once the desired number of throws has been placed, the suture material is then pulled taught, leading to complete or partial closure of the wound, and tied utilizing an instrument tie. Alternatively, a hand tie may be used if desired.

For a detailed discussion of the advantaged and applications of this technique, see the section above on the buried purse-string technique. A monofilament suture is generally used to permit easy pull-through as well as straightforward suture removal.

The purse-string technique may also be used to affect hemostasis in the case of an oozing wound. For wounds in highly vascular areas, such as the scalp, a purse-string suture may be performed distant from the wound edge; small vessels will be captured within the ring of the purse-string suture and compressed when the suture material is tightened, leading to improved hemostasis. A double ring of purse-string sutures may be used as well to take even better advantage of this hemostatic effect.

VARIATIONS

Running

Running suture techniques are frequently used for their rapidity and ease of placement. The classic technique is the simple running suture (Fig. 13-28), where anchoring sutures are placed at one end of the wound and successive bites are taken moving along the wound. Whether each bite is oriented perpendicularly or diagonally relative to the incision line is largely a point of style.

Figure 13-28. The simple running suture technique.

The running horizontal mattress suture, possibly with intermittent single bites, is another useful technique that leads to excellent wound-edge eversion (Fig. 13-29). A running vertical mattress technique is also possible, though it is used less frequently.

Figure 13-29. The running horizontal mattress technique.

The advantage of running techniques is that they are fairly quick to place, as individual knots are not needed for each suture bite. This is also their central disadvantage, since the entire suture line is secured by only two knots, and if either one is compromised then the integrity of the repair is lost.

Locking

Locking suture techniques, frequently used in concert with running techniques, allow the suture material to be fixed in place. They are frequently used with a simple running suture (the running locking or locked suture), which maintains even tension over each of the suture loop so that bunching and differential tension is less likely. This technique has also been suggested as an adjunct to achieving hemostasis. Other techniques, such as the horizontal mattress suture, may be locked as well, though in practice, this is performed less frequently.

Figure 13-30 shows approaches to hemostasis using a figure-of-eight suture or direct ligature.

Figure 13-30. Approaches to hemostasis using a figure- of-eight suture or direct ligature.

CONCLUSIONS

Meticulous suturing technique is the cornerstone of every surgical repair. While the dermatologic surgeon does not need to incorporate a vast array of techniques into daily practice, precise placement of sutures coupled with an appreciation of the subtle variations in individual patients that may benefit from particular niche techniques is very helpful and may result in improved surgical outcomes.

CHAPTER 14 Superficial Biopsy Techniques

Dirk M. Elston

SUMMARY

- The biopsy of tissue for histological exam remains one of the most informative and cost-effective tests in medical practice, and one of the most common procedures performed by dermatologists.
- In general, all tissues removed during a surgical procedure should be submitted for histopathologic examination.
- Ultimately, the key factor in biopsy success is balancing the need for acquiring an adequate sample for histopathologic evaluation with minimizing the cosmetic and functional sequelae of the biopsy itself on the patient.

Beginner Pearls

- Local anesthesia is a prerequisite for a pain-free biopsy; while patients may rarely request that a biopsy be performed without anesthesia, this should be discouraged, particularly as postbiopsy hemostasis may be more painful than the biopsy itself.
- Patients should receive written instructions regarding wound care.
- Shave biopsies are the cornerstone of dermatologic practice, and are useful in most situations when performed appropriately.

Expert Pearls

- The “excisional biopsy” that is recommended for pigmented lesions suspicious for melanoma includes a deep shave or scoop biopsy.
- Multiple scouting biopsies may be useful when assessing for lentigo maligna.

Don't Forget!

- When sampling for direct immunofluorescence, a punch biopsy from lower extremity skin should generally be avoided both due to a risk of false-negative results and a slower rate of healing.
- For alopecia, punch biopsy for transverse (horizontal) and vertical sections should ideally be performed.

Pitfalls and Cautions

- Often the greatest risk associated with a biopsy is not performing it at all; in the hands of experienced dermatologic surgeons, small biopsies yield nearly undetectable scars, and the diagnostic benefits far outweigh the risks.
- Biopsies from sebaceous skin, such as the nose, may leave pronounced scars that may benefit from later dermabrasion or resurfacing.

Patient Education Points

- Most biopsy sites heal very quickly, but patients should understand that surrounding erythema or excess fibrin formation may be seen, particularly in areas that are subject to friction.
- Preoperative biopsy-site photography may be helpful to reduce the risk of surgical site identification challenges.

Billing Pearls

- Biopsy coding is predicated on the assumption that the purpose of tissue removal is for diagnostic purposes.
- Site-specific biopsy codes should be utilized as appropriate.

CHAPTER 14 Superficial Biopsy Techniques

INTRODUCTION

The biopsy of tissue for histologic examination remains the most informative and cost-effective test in medical practice and one of the most common procedures performed by dermatologists. Usually, a visible lesion is biopsied, but multiple random skin biopsies from the abdomen and thighs may be helpful in the setting of angiotropic lymphoma presenting as fever of unknown origin¹, to obtain tissue for fibroblast culture to assess for a genodermatosis,² or to assess the possibility of immunobullous disease in a patient with generalized pruritus. Reflectance confocal microscopy can be useful to localize the best area to biopsy in a large, poorly defined lesion.³ A range of biopsy techniques are available to the clinician (Fig. 14-1).

Figure 14-1. A range of biopsy techniques are available.

All tissues removed during a surgical procedure should be submitted for histopathologic examination unless specifically exempted by an

organization's Tissue Committee policy. Such policies typically exempt certain tissues of limited diagnostic value such as femoral head, teeth, nails, and cyst contents. Skin tags are sometimes on the exempt list, but caution is advised, as infundibulocystic basal cell carcinoma, neurofibromas, and fibrofolliculomas may have a tag-like appearance. Any unusual-appearing tag should be submitted for examination, even if Tissue Committee policy exempts them.

Anesthesia, preparation, and postoperative care

Prior to any biopsy, local anesthesia should be obtained by the use of lidocaine. Epinephrine is typically added at a dilution of 1:100,000 or 1:200,000 to induce vasoconstriction, and the lidocaine is frequently buffered with sodium bicarbonate to reduce the burning sensation during injection. Data vary regarding whether warming or chilling the lidocaine solution results in less pain during injection, with some data favoring either method. Slow injection, vibration, application of an ice cube, or pinching of the skin can all be used to decrease the pain involved with injecting the local anesthetic (Table 14-1).

Table 14-1. Techniques to Minimize Biopsy-Site Injection Pain

Slow injection
Vibration
Application of an ice cube
Pinching of adjacent skin

Superficial dermal injection may be more painful, though it provides instant and total anesthesia, while deeper injections hurt less, but take time for complete anesthesia to take effect. Lidocaine is vasodilatory and the vasoconstrictive effects of epinephrine take several minutes to take effect. Thus, biopsy before the onset of action of epinephrine may result in excessive bleeding. Buffered lidocaine has a finite shelf-life (roughly 1 week), and outdated solutions produce only partial anesthesia with excessive bleeding.

Biopsy sites in periorificial areas as well as the lower leg are more prone to infection. For these sites, some clinicians will add 0.15 mL of clindamycin, 150 mg/mL to 50 mL of buffered lidocaine with epinephrine to achieve a concentration of 408 mcg/mL, which has been shown to reduce the rate of local infection.⁴

Correct positioning of the patient is essential. If a biopsy site is likely to bleed, a clean barrier should be placed under the affected area. The area should be clean and well organized with all instruments in place, the biopsy bottle open and labeled with the patient's name, date of birth, and biopsy site, and gauze, hemostatic solution (typically 20% aluminum chloride or Monsel's solution), white petrolatum, and a band-aid already positioned. The surgical assistant should read the site on each bottle before the specimen is placed into the formalin to assure that it is going into the correct bottle. The specimen should be fully immersed in the formalin solution, and visual inspection by the physician should confirm it is in the bottle before the cap is applied.

For biopsies on the head and neck, caustic hemostatic agents should be used with extreme caution near the eyes. A cotton-tipped applicator (CTA) should be dipped into the cautery solution and rolled dry so that drips are unlikely. For lesions near the eyes, the patient should be positioned so that gravity and creases will not draw the hemostatic solution into the eye. The wound should be blotted dry immediately after the biopsy and a CTA moistened with hemostatic solution rolled gently over the site, rather than twisted into the tissue. The wound surface should then be blotted to remove any excess hemostatic solution, as it will otherwise continue to burn the tissue and produce excess scarring.

Monsel's solution has the potential to cause a visible tattoo and must be used in a precise fashion. The wound must be blotted completely dry and the moistened CTA rolled quickly over the surface to obtain hemostasis. Incorrect application of excessive Monsel's solution to a bleeding wound results in a heavy black crust with continued bleeding through the crust, whereas a barely moistened CTA rolled across a dry wound produces instant hemostasis with little risk of tattoo.

Patients should receive written instructions regarding wound care. Most wounds can be cleaned with soap and water, then covered with white petrolatum and a bandage. Antibiotic ointments carry a risk of contact allergy

and anaphylaxis, and make gram-negative wound infection more likely.⁵ An exception is often made for wounds with exposed cartilage, which may be treated with topical gentamycin ophthalmic ointment or 0.025% acetic acid compresses twice daily to reduce the risk of *Pseudomonas* chondritis. Patients should be instructed to expect shave biopsy sites to become red around the edges and slightly yellow in the center during wound healing, and should be reassured that this does not represent infection.

TECHNIQUE

Shave

Biopsies using a shave technique are commonly used to sample neoplastic lesions, but may also be useful in the setting of inflammatory dermatoses if the key histologic features are present in the epidermis and papillary dermis. Engineered sharps (Fig. 14-2) should be considered whenever possible to reduce the risk of injury to members of the care team, though currently available engineered sharps are less rigid than traditional double-edged razor blades and often cannot substitute. Thus most dermatologic surgeons continue to prefer the use of either double- or single-edged razor blades. Others prefer the use of a number 15 or number 10 blade followed by curettage to smooth the wound edges.

Figure 14-2. Shave biopsy technique. The skin is held taut with the nondominant hand, and the fourth finger of the dominant hand may provide additional stabilization.

The technique. The skin is pulled taught in all directions by the surgeon, and an assistant if needed. This allows for more precise sampling of the tissue, a smoother wound edge, and quicker sampling. A shave that won't end, producing a tail, is usually the result of failure to pull the skin taught. The blade is initially angled slightly downward to breach the epidermis, carried horizontally to obtain the specimen, then angled upward to complete the procedure. A fairly rapid but gentle side-to-side motion allows the blade to move smoothly through the tissue without causing ridges. A tumid technique has also been described which involves ballooning of soft papules such as benign nevi and neurofibromas with a mixture of lidocaine diluted with bacteriostatic 0.9% sodium chloride to create a more rigid structure and facilitate shave removal.⁶

Saucerization

When performed properly, saucerization, or scoop shave removal, results in an eponymous saucer-shaped specimen with complete extirpation of the lesion (Fig. 14-3). Saucerization may remain in the dermis or be scooped to subcutaneous tissue.

Figure 14-3. Saucerization biopsy is essentially a deep shave biopsy. This is a preferred technique for suspicious pigmented lesions.

The technique. The overall technique is very similar to a shave biopsy, but the blade is angled more steeply toward the center of the biopsy site, then advanced with a similar rapid but gentle side-to-side motion and a forward scooping motion. Some clinicians prefer to score the skin around the target lesion top aid with an aggressive saucerization. Often, pinpoint-bleeding dermis is visible immediately after a saucerization biopsy (Fig. 14-4).

Figure 14-4. Often, pinpoint-bleeding dermis is visible immediately after a saucerization biopsy.

Punch

The punch technique can be used to sample an inflammatory process, a lesion, or for complete excision of a smaller lesion. Furthermore, lesions slightly larger than 4 mm can often be forced into a 4-mm punch, resulting in satisfactory removal or sampling and a smaller wound.

The technique. When possible, the skin is pulled taught perpendicular to the skin tension lines, so that the wound created by the punch is oval and aligned with the preferred lines of closure. The punch is twisted gently (Fig. 14-5) until the full thickness of the metal portion has entered the skin (Fig. 14-6). The resulting specimen should be removed gently with a needle or by grasping the skin edge with toothed forceps to avoid crushing the specimen (Fig. 14-7). The resulting defect should then be assessed for the ideal closure vector (Fig. 14-8). A suture is placed (Fig. 14-9) and the wound may be closed with either a simple interrupted suture or a cruciate mattress suture (Fig. 14-10). Other novel punch biopsy devices are available as well.⁷

Snip

Figure 14-5. The punch is twisted gently.

Figure 14-6. This continues until the entire device is inserted (when working on the trunk) or once the deep fat has been entered, as seen here.

Figure 14-7. The specimen is grasped with forceps, elevated, and the base is snipped if needed at the level of the deep fat.

Figure 14-8. The resulting oval defect should be assessed for the ideal closure vector.

Figure 14-9. A suture is placed.

Figure 14-10. The cruciate mattress suture, essentially two throws of a simple running suture, is useful for punch biopsy closures.

A snip biopsy is performed by utilizing surgical scissors, such as gradle scissors, to remove a pedunculated lesion, generally at its base. After local anesthesia is obtained, care should be taken to avoid elevating the target of

the biopsy with forceps, as a snip biopsy at the base of a manipulated pedunculated papule will result in a depressed postprocedure scar. Instead, the papule should be snipped at its base in the resting position, which should result in minimal postprocedure scarring.

Incisional biopsy

Incisional biopsies allow the surgeon to have full control over the size, shape, and depth of the specimen and are typically followed by straight-line closure. Panniculitis is best diagnosed by an incisional biopsy, although double-punch and other related techniques have also been used.⁸ Large melanocytic lesions are also often approached in this manner.

The technique. A straight line or elliptical incision is made and the desired portion of tissue is removed (Fig. 14-11). The resulting defect is then similar to any other created in excisional surgery (Fig. 14-12), and the wound is closed with simple or layered closure.

Figure 14-11. An incisional biopsy is useful particularly when a deep melanoma is being sampled to assess the depth of invasion.

Figure 14-12. The resultant defect may then be approached in a similar fashion to any other excisional surgery.

Excision

Excision is the most appropriate technique to produce tissue for examination when the lesion is most likely malignant and subtotal excision may compromise diagnosis or outcome.

The technique. The tissue is removed through the subcutaneous tissue by means of elliptical, circular, or scooped excision. Undermining is often required to free the wound edges to facilitate closure. The wound is closed with simple or layered closure.

Fine-needle aspiration

Fine-needle aspiration (FNA) has been used to sample lymph nodes, soft tissue masses, and even superficial tumors.⁹ The major disadvantage of this technique is that the architecture of the lesion cannot be evaluated. Assessment of architecture is often key to the diagnosis of cutaneous neoplasms as well as inflammatory dermatoses, and FNA is rarely

performed in the dermatologic surgery context unless no other option is available.

Coding for biopsies

The procedure is correctly reported as a biopsy when the clinician's intent is to sample a portion of the lesion for diagnosis, regardless of the technique used. A procedure is correctly coded as a shave when the clinician's intent is complete removal of the lesion, and dermis remains at the base of the wound (Fig. 14-4). A procedure is correctly coded as excision when the clinician's intent is complete removal of the lesion and no dermis remains at the base of the wound. For a full discussion of coding options, see [Chapter 10](#).

SPECIAL SITUATIONS AND SPECIAL SITES

Pigmented lesions

The American Academy of Dermatology (AAD) and the National Comprehensive Cancer Network (NCCN) list narrows excisional biopsy as the preferred technique for sampling lesions suspicious for melanoma. Importantly, saucerization, or a scoop-shave technique, is suitable for thin melanocytic lesions and rarely compromises staging,^{10,11} and indeed, the AAD guidelines themselves include saucerization as a technique to accomplish an excisional biopsy.

In a study of 332 melanoma patients, most diagnostic biopsies had positive margins regardless of biopsy technique, but staging changed in only 8% of patients, of whom 59% had a punch biopsy, 15% an incisional biopsy, 15% a shave biopsy, and 11% an excisional biopsy ($P < 0.0001$). Treatment recommendations changed in 6% of the patients: 2% after excisional biopsy, 5% after shave biopsy, 18% after punch biopsy, and 18% after incisional biopsy ($P < 0.0001$).¹² These data suggest that scoop-shave technique on an appropriately chosen lesion can be a prudent choice, but punch biopsy should be discouraged.

Another study of 709 patients showed that shave biopsies resulted in more positive deep margins ($P < 0.001$). Both shave and punch biopsies resulted in more positive peripheral margins ($P < 0.001$) and a higher risk of finding

residual tumor on wide local excision ($P < 0.001$), but biopsy type did not confer survival advantage or impact tumor recurrence, suggesting that experienced clinicians should be free to choose the most appropriate technique for a given lesion.¹³ Other authors have published data supporting similar conclusions.^{14,15}

In the setting of lentigo maligna, it is often impractical to remove the entire lesion, and sampling of the lesion may be more appropriate. A broad area of the dermal–epidermal junction may be demonstrated by a broad, thin biopsy resembling properly cut prosciutto. If the lesion is mottled with many colors, multiple small thin shaves sampling each color may be more appropriate. If a skin crease naturally traverses the area to be sampled, an incisional biopsy can be aligned along the crease.

Immunobullous disease

In the setting of suspected immunobullous disease, biopsies for direct immunofluorescence should be taken from nonbullous lesional skin or perilesional skin within about 1 cm of a bulla. Nonbullous lesional skin has the higher yield.¹⁶ Lower extremity skin should be avoided because of a greater risk of false-negative results.^{17,18} Specimens for light microscopy should demonstrate an intact vesicle or bulla whenever possible. For larger lesions, the specimen should contain both portions of the blister and intact skin so that the edge of the blister and a portion of the bulla. A punch biopsy or shave excision works well for small vesicles, while a scooped shave may be useful to harvest larger bullae intact.

Tissue obtained for direct immunofluorescence should be placed in Michel's medium or Zeus medium.^{19,20} Some immunodermatology laboratories prefer specimens transported in saline to reduce background staining. Saline-preserved specimens should be processed within 24 hours. If the specimen is inadvertently placed into formalin, it should immediately be removed and rinsed in normal saline. Brief formalin immersion produces false-negative results for pemphigus, but not for diseases characterized by deposits at the dermal–epidermal junction.²¹ In the setting of tense blisters suggesting a subepidermal bullous disease, a single punch technique has been used to obtain both H&E and DIF specimens and provide salt-split, skin like diagnostic information.²²

Connective tissue disease

In contrast to immunobullous disease, biopsies of suspected connective tissue disease for DIF are best demonstrated in well-established lesion >6 months old. In the setting of systemic LE, the lupus band test performed on normal sun-protected skin has largely been replaced by assays for double-stranded DNA antibodies which identify the same population at risk for renal disease.

Vasculitis

In the case of suspected vasculitis, biopsies for H&E should be taken from a well-established purpuric lesion (at least 72 hours old), while biopsies for DIF should be taken from an acute lesion (<24 hours old). IgA vasculitis is more likely to retain positive DIF findings in established lesions, when compared with other forms of vasculitis.

Alopecia

To maximize the diagnostic yield in the setting of alopecia, a 4-mm punch biopsy specimen should be obtained from a well-developed lesion, preferably of several months' duration, but still active. Many labs prefer transverse sections, although serial vertical sections are superior in the setting of scarring alopecia. A separate biopsy can be bisected vertically to produce a half punch suitable for DIF and another half punch added to the formalin bottle to provide vertical sections. When biopsies of active lesions prove to be nondiagnostic, a biopsy from a scarred area evaluated with elastic tissue stains or polarized microscopy can provide additional information.^{23–26} Both trichoscopy and confocal microscopy can be useful in site selection, directing the clinician to established areas of active inflammation.^{27–29} The punch should always enter the scalp at the same angle as the emerging hairs to avoid transecting hair follicles. Hemostasis is more easily obtained with gel foam than with sutures.

Mucosal and genital biopsies

The thin skin of the lips has a tendency to retract when a shave biopsy is performed. Therefore, utilizing a tumid-type technique, raising a significant wheal in the target tissue, may serve to develop a more rigid substrate for shave biopsy. Alternatively, a chalazion clamp may be used, a snip biopsy may be performed after grasping the target tissue with dressing forceps, or a punch biopsy may be performed in lieu of a shave approach. Similar approaches may be used when performing biopsies on the vulva or shaft of the penis.

CONCLUSIONS

Careful attention to biopsy technique, patient positioning, site selection, and hemostasis will result in better outcomes for the patient and a more efficient practice for the clinician. Ultimately, the key factor in biopsy success is balancing the need for acquiring an adequate sample for histopathologic evaluation with minimizing the cosmetic and functional sequelae of the biopsy itself on the patient.

CHAPTER 15 Cryosurgery

Carolyn Stull
Clifford Perlis

SUMMARY

- Cryosurgery is a versatile technique and a mainstay of the dermatologic surgeon's therapeutic armamentarium.
- While used largely for actinic keratoses, cryotherapy may be used for an array of dermatologic conditions.
- Cryosurgery has become a well-established, safe treatment modality for a wide range of conditions, and will likely remain a fixture in dermatologic surgery for years to come.

Beginner Pearls

- It is always better to undertreat than overtreat an area. Warn patients that the areas being treated may not resolve and that additional treatments may be needed.
- Localize tissue treatment to the area of concern; it is best to avoid overly broad treatment that only serves to cause more tissue damage.

Expert Pearls

- Intralesional cryoneedles and other similar approaches may be used to treat larger or more aggressive tumors.
- In such cases, accurately gauging the temperature at the deepest section of the target lesion may be helpful.

Don't Forget!

- Melanocytes are highly cold-sensitive, while malignant cells are most resistant to cold-induced damage. Therefore, pigmentation changes are seen frequently with even moderately aggressive cryosurgery.
- Cryosurgery induces tissue necrosis through several pathways, including direct cellular injury, intra- and extracellular ice deposition, and damage to the microcirculatory vasculature.

Pitfalls and Cautions

- Healing time after cryosurgery varies, and patients will almost always have significant edema and erythema in the immediate postprocedure period.
- On the scalp and legs, sites may take significantly longer to heal adequately.

Patient Education Points

- When treating actinic keratoses, there is often a field of actinic damage where incipient actinic keratoses are forming. Additional actinic keratoses in this area may be a result of this actinic field injury rather than a recurrence due to inadequate cryosurgery.
- Patients should be told what to expect in the posttreatment period to minimize anxiety.

Billing Pearls

- Cryosurgery coding depends on the lesion and anatomic site being treated. For actinic keratoses, use code 17000 for the first lesion and 17003 for each additional (up to 14), and code 17004 if 15 or more are treated. For warts and other benign lesions, use code 17110 (a single code for up to 14 lesions) or 17111 (15 or more). For genital lesions, use code 54056 for the penis or 56501 for the vulva. For malignant destruction, use the 172XX series.

CHAPTER 15 Cryosurgery

INTRODUCTION

Cryotherapy, the application of cold temperatures for therapeutic purposes, has been utilized for thousands of years. Historical records dating as far back as 2500 BC reveal that the Egyptians used cold to treat injuries and infected wounds.¹ In the 5th century BC, Hippocrates documented the analgesic and anti-inflammatory properties of this modality.² However, the technique of cryosurgery, which specifically denotes the use of extreme cold for cellular destruction, has its origin in more modern times. Around the turn of the 20th century, Dr. Campbell White, a dermatologist in New York, first pioneered the use of liquefied air for the treatment of warts, nevi, and malignancies. In subsequent years, cryogen delivery was enhanced with the development of handheld spray units and the availability of liquid nitrogen. Currently, cryosurgery exists as an extremely versatile treatment modality that is indicated for the treatment of numerous benign, premalignant, and malignant lesions.

CRYOGENS

Presently, liquid nitrogen is used exclusively in the vast majority of dermatology settings. However, prior to its development, several other cryogenic substances were employed for similar purposes. The original cryogen was liquefied air (-190°C), which was composed of approximately 78% nitrogen, 21% oxygen, 1% argon, with traces of other gases.^{2,3} While effective, liquid air was difficult to obtain, and was subsequently superseded by solidified carbon dioxide (-78.5°C) in the early 1900s.⁴ In the 1920s, liquid oxygen (-182.9°C) became readily available, but its use was limited

by safety concerns including flammability.⁵ The use of liquid nitrogen (-195.6°C), which remains the most frequently employed cryogen, was first reported in 1950.³ In contrast to liquid oxygen, liquid nitrogen is inert, and is considered to be both safe and effective.

INSTRUMENTS

There are a variety of methods that may be used to apply liquid nitrogen. The most common of these in dermatologic settings is the use of a handheld spray unit (Fig. 15-1). These units are available in multiple sizes and with several modifications that allow cryogen delivery to be tailored according to circumstance. Techniques of spray delivery include direct application to the center of a lesion, a spiral pattern that begins in the center and radiates outward, and a “paintbrush” pattern in which the nozzle is moved back and forth from one side to another. Various tips are available for these units (Fig. 15-2). Devices such as an insulated plastic cone may be used in conjunction with the spray method to increase the concentration of liquid nitrogen applied to a particular location. The cone is placed directly onto the skin, and enhances both the rate and depth of freezing.

Figure 15-1. The liquid nitrogen spray unit.

Figure 15-2. Various tips are available for the units.

To increase both the depth and lateral extent of freezing, cryoprobes may be used. Cryoprobes are tips cooled by circulating cryogen that can be inserted directly into the skin. They are available in a variety of shapes and sizes, and are particularly useful for treating sebaceous hyperplasia and small vascular lesions. Additionally, cryoprobes are well suited to treat small tumors on the eyelid or lip where fine-tuned control of cryogen delivery is essential.⁶

A variation of the probe technique, the intralesional cryoneedle, may be useful for solid masses. This device can be passed through a tumor until the tip reemerges on the opposite side. Liquid nitrogen is circulated through the lumen of the needle, forming an ice cylinder in the surrounding tissue that expands circumferentially. The advantage of this technique is that colder temperatures may be applied directly to deeper structures, rather than the skin surface.⁷ This method may be especially useful for the treatment of hypertrophic scars and keloids.⁸

The dipstick method, in which a cryogen-soaked cotton swab is applied directly to the skin, may also be useful. This technique is most suitable for the treatment of benign, superficial lesions, as the maximum depth of freezing achieved is 2 to 3 mm.

TECHNIQUES

While there are no absolute contraindications to cryosurgery, some comorbidities are more likely to be associated with adverse outcomes. Some of these include known cold intolerance, cold urticaria, cryofibrinogenemia, cryoglobulinemia, and Raynaud's phenomenon. Collagen vascular disease, multiple myeloma, hemodialysis, thrombocytopenia, agammaglobulinemia, and blood dyscrasias of unknown origin have also been noted as relative contraindications.⁹

Several factors affect the amount of tissue destruction achieved with cryosurgery. When tissue is frozen, an ice ball forms that serves as a visible indication of the extent of surface freezing (Fig. 15-3). However, the depth of freezing, also referred to as the depth dose, may be more difficult to determine. The ice ball maintains a hemispherical shape until it reaches a

depth of 5 to 7 mm, at which point it will begin to plateau. For lesions exceeding this depth, a thermocouple may be useful. This device should be inserted into the skin at a 25- to 30-degree angle until the tip reaches the base of the lesion, and will provide a more accurate determination of tissue temperature, though these are rarely used in clinical practice.

Figure 15-3. When tissue is frozen, an ice ball forms that serves as a visible indication of the extent of surface freezing.

The temperature achieved with cryosurgery is directly related to the degree of resultant cellular injury. Melanocytes are most sensitive to cold, and are irreversibly damaged at temperatures ranging from -4° to -7°C . Keratinocytes are destroyed at temperatures ranging from -20° to -30°C , and death of fibroblasts occurs between -30° and -35°C . Malignant cells are most resistant to cold-induced damage, requiring temperatures below -40°C for destruction.¹⁰ Therefore, when treating a malignancy, a temperature endpoint between -50° and -60°C is advisable (Fig. 15-4).

Figure 15-4. There is marked variability in the cold sensitivity of different cell types.

The freeze time, or duration of cooling, is another important consideration. In general, benign lesions require shorter freeze times, and may be sufficiently treated with a single freeze–thaw cycle. Malignancies often require a double freeze–thaw cycle, and freeze times exceeding 45 seconds.

Additionally, the lateral spread of freeze, or margin of freeze, varies depending on the type of lesion. For benign lesions, margins of 2 to 3 mm are sufficient, whereas malignant lesions may require margins of 5 mm or more.

Certain adverse responses, such as pain and blistering, should be anticipated following cryotherapy; when these become intolerable or progress to longer-term effects, they may be considered complications.

In the absence of local anesthetic or pre-existing neuropathy, all patients will feel pain during the treatment. Many patients will describe burning or stinging pain initially that may progress to a dull throbbing pain. The pain usually resolves spontaneously within minutes. Treatments to certain parts of the body, such as the ear, finger tips, lips, temples, and scalp may cause more severe pain. Additionally, cryosurgery to the scalp, temple, or forehead may occasionally be associated with migraine-like headaches.⁹

Almost all treated patients will also develop localized edema, blister formation, and erythema (Fig. 15-5). The amount of edema is related to both the intensity of the treatment and the lesion location. The eyelids, labia minora, lips, and foreskin have more lax skin and therefore develop greater edema.⁹

Figure 15-5. Almost all treated patients will also develop localized edema, blister formation, and erythema. Note the immediate postprocedure erythema.

Hypopigmentation is perhaps the most common complication. One prospective study of 421 actinic keratoses treated with cryosurgery reported hypopigmentation in 29%. The incidence of hypopigmentation increased with the duration of freezing time.¹¹ This may stem mechanistically from the fact that melanocytes are more cold-sensitive than keratinocytes and fibroblasts.

Hypopigmentation is especially common in those with darker skin types. Paradoxically, hyperpigmentation may also develop following cryosurgery-induced inflammation.

Sensory and motor neuropathy may also develop following cryosurgery. The extent of neuropathy will depend on the cryosurgery dose and lesion location. One study of sensory neuropathy associated with cryotherapy revealed complete recovery in all subjects by 18 months.¹² Infection, atrophy, hemorrhage, milia, hypertrophic scarring, bone necrosis, ectropion, and alopecia are additional reported complications.⁹

MECHANISM OF ACTION

Cryoablation induces tissue necrosis through multiple mechanisms including direct cellular injury, apoptosis, vessel thrombosis, and immune response activation. Direct cellular injury occurs through the formation of intracellular and extracellular ice (Fig. 15-6). Intracellular ice results in the destruction of cell membranes and vital organelles, and is maximized by rapid freezing. Extracellular ice alters the osmotic gradient between cytoplasm and extracellular fluid. Together, these changes result in irreversible cell death. Cellular damage continues during the thawing phase, in which the formation of large ice crystals imposes shearing forces on surrounding tissue. To maximize the damage accrued during recrystallization, thawing should proceed as slowly as possible.¹³

Figure 15-6. Direct cellular injury occurs through the formation of intracellular and extracellular ice.

In addition to direct cellular injury, cryosurgery also has a destructive effect on microcirculatory vasculature. Freezing causes damage to capillary endothelial cells, resulting in platelet aggregation and thrombosis of papillary dermal vessels. Additionally, freezing destroys mast cell membranes and causes degranulation, which results in histamine-mediated increases in capillary permeability. Subsequent vasodilation results in increased edema and inflammatory cell infiltration.

The immunologic effect of cryosurgery is less well defined. Evidence of a systemic immune reaction is found in reports citing resolution of multiple verrucae after cryosurgical treatment of only a few lesions—an abscopal response. This reaction is likely incited by the release of DNA, RNA, uric acid, and other intracellular elements following the destruction of cell membranes. These elements activate toll-like receptors, triggering subsequent immunologic cascades. An innate immune response is generated initially, resulting in early infiltration of granulocytes, monocytes, and macrophages. An adaptive immune response follows, in which dendritic cells travel to regional lymph nodes to undergo maturation and antigen presentation.¹⁰

INDICATIONS

Cryotherapy has been reported for a broad range of dermatologic conditions including malignant, infectious, autoimmune, and inflammatory conditions.¹⁴ General guidelines recommend a single freeze–thaw cycle for treating benign conditions. This approach is less likely to lead to poor healing or scarring, and treatment can be safely repeated at a later date since the condition is benign. The majority of published findings for treating many of the listed conditions consist of case reports or small uncontrolled series, though larger studies exist for the treatment of basal cell carcinoma, squamous cell carcinoma, and actinic keratoses have been performed. [Table 15-1](#) is a summary of benign conditions treated with cryotherapy and [Table 15-2](#) is a summary of malignant and premalignant conditions treated with cryotherapy.

Table 15-1. Benign Conditions Treated with Cryotherapy

Acne	Granuloma annulare	Porokeratosis plantaris discreta
Acne keloidalis	Granuloma faciale	Porokeratosis of Mibelli
Adenoma sebaceum	Granuloma pyogenicum	Prurigo nodularis
Alopecia areata	Hemangioma	Pruritus ani
Angiokeratomas	Herpes labialis	Psoriasis
Angiokeratoma of Fordyce	Idiopathic guttate hypomelanosis	Rhinophyma
Atypical fibroxanthoma	Kyrle's disease	Rosacea
Cherry angiomas	Leishmaniasis	Sarcoid
Chondrodermatitis nodularis helices	Lentigines	Sebaceous hyperplasia
Chromoblastomycosis	Lentigo simplex	Seborrheic keratosis
Clear cell acanthoma	Lichen sclerosus et atrophicus	Solar lentigo
Condyloma acuminatum	Lupus erythematosus	Syringoma
Dermatofibroma	Lymphangioma	Trichiasis
Disseminated superficial actinic porokeratosis	Lymphocytoma cutis	Trichoepithelioma
Elastosis perforans serpiginosa	Molluscum contagiosum	Varicose veins
Epidermal nevus	Mucocele	Venous lake
Erosive adenomatosis of the nipple	Myxoid cyst	Verrucae
Folliculitis keloidalis	Orf	Xanthoma

Table 15-2. Malignant and Premalignant Conditions Treated with Cryotherapy

Actinic cheilitis
Actinic keratosis
Bowen's disease
Erythroplasia of Queyrat
Keratoacanthoma
Lentigo maligna
Squamous cell carcinoma in situ
Basal cell carcinoma
Squamous cell carcinoma

Warts

Verrucae vulgaris are commonly treated with cryosurgery. A 2014 Cochrane review analyzed 21 studies of cryosurgery for treating warts.¹⁵ Meta-analysis of cryosurgery versus placebo failed to show a statistically significant difference; 41 of 107 (38.3%) of warts resolved with cryosurgery. The largest and the most recent of the included studies comparing cryosurgery to placebo did, however, demonstrate a therapeutic advantage to cryosurgery. Thirty of 76 (39.5%) warts in the cryosurgery group responded compared to 13 of 82 (15.9%) in the placebo group.¹⁶ Furthermore, treatment intervals

every 2, 3, or 4 weeks did not impact cure rates. Aggressive cryotherapy was, however, more effective than gentle cryotherapy. Aggressive cryotherapy was also associated with a higher incidence of pain and blistering.¹⁷

Seborrheic keratoses

Cryosurgery is a well-described therapy for seborrheic keratoses. It is critical, however, that the clinical, or preferably histological, diagnosis is confirmed prior to treating with cryotherapy. One study comparing curettage to cryotherapy revealed that 15 of 25 subjects (60%) preferred cryotherapy, while 9 of 25 (36%) preferred curettage. Even though cryotherapy was associated with increased pain, subjects preferred this modality largely due to the decreased requirement for postoperative wound care. Self-reported cosmesis was reported to be the same between the two groups. Physician evaluation showed that there were more redness and tendency for hypopigmentation in the curettage group, and more frequent residual seborrheic keratoses in the cryotherapy group.¹⁸

More recently, a randomized prospective trial of 120 seborrheic keratoses compared cryosurgery to an erbium: YAG laser for treating seborrheic keratoses. Following the first treatment session, 100% of the Er:YAG-treated lesions resolved, while only 63.8% of those treated by cryosurgery completely responded. Both groups received topical anesthesia with EMLA cream prior to treatment, and neither group reported severe pain or interrupted therapy due to pain.¹⁹

Granuloma annulare

Granuloma annulare is another benign condition effectively treated with cryosurgery. A single freeze–thaw treatment cycle lasting 10 to 60 seconds using either liquid nitrogen or nitrous oxide leads to lesion resolution in 25 of 31 (80.6%) of patients. All patients developed blisters within 24 to 48 hours of treatment. Cryoatrophy (14.3%) and dyspigmentation (7.1%) were the most commonly reported adverse effects. Significantly, cryoatrophy developed in 21% of subjects treated with liquid nitrogen and none of the subjects who received nitrous oxide.²⁰

Actinic keratoses

Actinic keratoses are a well-described and widely practiced indication for cryotherapy. Lesions may be treated with a cryospray or by using a cotton-tipped applicator, though the latter is now used infrequently. One study from 1982 reported a 98.8% cure rate in the treatment of 1018 actinic keratoses in 70 patients. At follow-up ranging from 1 to 8.5 years after the treatment, 12 recurrences were noted.²¹ Cryosurgery is often the treatment of choice for discrete lesions given its quick treatment time, wide availability, and minimal expense. A more recent Cochrane Database review from 2012 evaluated various available fields and individual lesion therapies for actinic keratoses. Photodynamic therapy, compared to cryotherapy, was more effective and yielded an improved cosmetic outcome for treating individual actinic keratoses.²² This finding should, however, be weighed against the convenience and cost-effectiveness of cryotherapy.

Basal cell carcinoma

Much of the primary literature utilizing cryotherapy to treat basal cell carcinoma is over 30 years old. One study of 628 basal cell carcinomas treated between 1980 and 1984 reported a 5-year cure rate of 99%.²³ The authors note that most of the cancers were “small (<0.5 cm) to medium (0.5–2.0 cm)” or superficial. Additionally, lesions located in critical anatomic locations—such as medial canthus—were excluded. The treatment technique sometimes included preoperative treatment with a local anesthetic and curettage. Depending on the size and thickness of the tumors, freeze time varied from 40 to 90 seconds, and the authors preferred to include repeated freeze–thaw cycles.

A 2003 review of uncontrolled prospective studies of basal cell carcinomas treated with cryosurgery reported recurrence rates ranging from 0% to 21% for follow-up at 6 months to 10 years.²⁴ If the single study of 19 patients with eyelid tumors is excluded, the highest reported recurrence rate is 8.2%. Cosmesis was quantitatively evaluated in only two studies, but was generally commented on as “acceptable” to “excellent.” All studies were assigned a C grade, per Sackett’s rules of evidence, indicating lack of

randomization, placebo control, or blinding, and were case reports and case series.²⁵

In addition to problems with study design noted above, at least one author has challenged the previously reported high cure rates for two other reasons.²⁶ First, previous studies were not stratified based on histological subtype. In addition, the treatment techniques reported in the initial publications likely differ significantly from how cryotherapy is currently used. Most contemporary dermatologists are unlikely to debulk a tumor with curettage or electrosurgery prior to cryotherapy. Furthermore, contemporary dermatologists probably do not utilize freeze cycles as long as those previously reported. Accordingly, the cure rates from older studies may not be replicated in contemporary practices.

Squamous cell carcinoma

Data on cryotherapy for squamous cell carcinomas is similar to that found for the treatment of basal cell carcinomas in many respects. Pooled analysis of observational studies using cryotherapy reported only one recurrence (0.8%) out of 273 patients treated in 8 studies.²⁷ Mean follow-up ranged from 2 to 5 years. A retrospective series of 563 squamous cell carcinomas treated over a 23-year period described a 97% cure rate, though the definition of “cure” was unclear and no follow-up time was reported.²⁸ Of all the modalities included in the pooled analysis of observation studies for interventions for nonmetastatic cutaneous squamous cell carcinoma, cryotherapy along with electrodesiccation and curettage had the highest cure rates for squamous cell carcinomas, but most tumors were small and deemed to be low risk.²⁷ As with the studies on basal cell carcinoma, it’s not clear that the techniques employed for the studies—including debulking and prolonged freezing times—are the same techniques employed by contemporary dermatologists.

Lentigo maligna

Cryotherapy has also been described for the treatment of lentigo maligna. While clearly excision is preferable, the size, location, and comorbidities sometimes make excisional surgery impractical. At least three small case series describe cryosurgical treatment of lentigo maligna. One series of 30

patients with lesions measuring 1.3 to 4.5 cm treated between 1977 and 1992 reported two recurrences (6.6%).²⁹ This study utilized a double freeze–thaw cycle with 1-cm lateral spread. A study of 20 patients reported 2 recurrences (10%)³⁰, while another study of 20 patients reported 3 recurrences (15%).³¹ Contemporary dermatologists may treat lentigo maligna with cryotherapy less frequently due to both advances in reconstructive techniques as well as concerns with sampling error. Without the opportunity for histological evaluation, the presence of microscopic foci of lentigo maligna melanoma (which may occur in a significant proportion of cases) cannot be identified, and prognostic outcome cannot be predicted accordingly.

Kaposi sarcoma

Kaposi sarcoma, when limited to the skin, may respond well to cryosurgery. A retrospective cohort study of 30 patients was reported in 2013. Patients received two freeze–thaw cycles lasting 15 to 40 seconds/cycle with a 3-mm margin every 4 weeks. Nineteen (63%) patients experienced a complete response, eight showed a partial response, and three patients discontinued therapy due to an increasing number of lesions.³²

CONCLUSIONS

Cryosurgery has become a well-established, safe treatment modality for a wide range of conditions, and will likely remain a fixture in dermatologic surgery for years to come. New developments may include modifications in cryogen delivery methods and the refinement of temperature detection at the surface of the skin. Additionally, other techniques, including fractional cryosurgery, may become more widely employed, expanding the application of cryosurgery to larger tumors.^{33,34}

CHAPTER 16 Electrosurgery and Hemostasis

Michael Frank
Anthony V. Benedetto

SUMMARY

- Electrosurgery is a workhorse technique for dermatologic surgeons, with electrocautery and electrodesiccation representing the most frequently used techniques.
- Monoterminal units that function without a ground may be useful for many applications, but generally cannot be used for high-power applications or electrosection.

- Electrosurgery is a staple of dermatologic surgery practice, whether used for hemostasis, treatment of nonmelanoma skin cancer, or benign lesion desiccation.

Beginner Tips

- For most applications, electrocoagulation is the standard setting, and can be used with a monoterminal unit.
- Generally 40 watts is sufficient for small-vessel coagulation.

Expert Tips

- Electrosection may be useful for wide undermining.
- Do not use electrosection on any tissue that will be sent for histopathologic analysis in order to minimize the risk of artifact.
- Electrofulguration is an elegant technique in experienced hands to treat seborrheic keratoses, but as no tissue will be available for pathology the diagnosis must be absolutely certain before proceeding.

Don't Forget!

- Biterminal units always require that patients be in contact with a grounding plate, and most modern units are well isolated.
- Monoterminal units should never be used on sedated patients.
- Do not attempt to use ED&C to treat areas with a thin dermis, where full-thickness wounds will result.

Pitfalls and Cautions

- Larger electrosurgical units may generate significantly more power than smaller hyfrecators used in many offices.
- Never overreach by attempting to use electrosurgical approaches on a vessel that should be ligated with suture.

Patient Education Points

- Cure rates for low-risk nonmelanoma skin cancers with ED&C are very high, but are also highly operator dependent.

- Patients should realize that the tradeoff for a quick ED&C procedure is that the healing time postoperatively may be significantly longer than seen for surgical excisions.

Billing Pearls

- ED&C coding is based on the site and size of the entire skin cancer that was destroyed.
- Multiple sites treated in the same session would be added together for size, rather than billed individually.

CHAPTER 16 Electrosurgery and Hemostasis

INTRODUCTION

For millennia, heat has been used to treat tissue and control bleeding. Over time, the methods used have evolved, with the first widely available commercial electrosurgical unit released in the 1920s. Since then, the units have been refined dramatically, though the basic concept behind electrosurgery has remained the same. Details regarding the physics underpinning electrosurgical devices have been explored at length.¹⁻⁴

Terminology

Electrosurgery refers to the passage of high-frequency alternating electrical current through tissue to achieve a desired surgical effect, such as coagulation or cutting ([Table 16-1](#)). All true electrosurgical devices utilize a high-frequency electrical generator and two electrodes. Electric current flows from the active electrode through the patient's body and returns to the electrosurgical generator via the dispersive (return or indifferent) electrode ([Fig. 16-1](#)). When current passes through tissue, the tissue's resistance converts the energy into heat. This differs from electrocautery, which can be conceptualized as a directly heated metallic object, such as a hot iron. In electrocautery, instead of current flowing through the patient's body, electrical current directly heats a metallic probe that is then applied to the tissue ([Fig. 16-2](#)). Since no current passes through the patient, electrocautery is most commonly used when the operative site is near a patient's pacemaker,

defibrillator, or deep-brain stimulator, or to limit destruction to only the superficial tissue layers, since no heat is generated in deeper tissue.

Table 16-1. Common Methods of Electrosurgery and Their Definitions

Method	Definition
Electrosurgery	Electrical current is passed through tissue to achieve a specific surgical effect (i.e., cutting or coagulation)
Electrocautery	Electrical current heats a metal probe which is then applied to tissue
Electrocoagulation (contact coagulation)	Tissue is heated below the boiling point undergoing thermal denaturation
Electrodesiccation	At the end of coagulation, there is vaporization of the water content and drying of the superficial tissue layers
Electrofulguration (noncontact or spray coagulation)	Instead of making direct contact with the tissue, the active electrode is held a few millimeters above the tissue and electric current bridges the air gap as a spark
Electrosection	The tissue is quickly brought to a temperature above its boiling point causing tissue fragmentation and cutting
Electrosection, pure cutting	With pure cutting there is minimal/no coagulation of the incisional wall
Electrosection, blend cutting	With blend cutting there is more coagulation of the incisional wall
Bipolar electrosurgery	There are two active electrodes
Monopolar electrosurgery	There is one active and one return (dispersive) electrode
Biterminal electrosurgery	The active and return electrodes are in direct contact with the patient's body
Monoterminal electrosurgery	While the active electrode is in direct contact with the patient's body, the return electrode is not. It is connected to the earth and the earth acts as the return electrode

Figure 16-1. An electrosurgery unit. Current flows from the generator, through the active electrode and into the tissue. The tissue's resistance converts this energy into heat. The current then returns to the generator by way of a return (dispersive or indifferent) electrode.

Figure 16-2. An electrocautery unit. Unlike in electrosurgery, current simply heats the tip of the electrode, which is then applied directly to the tissue to heat the superficial tissue layers.

In electrosurgery, a small active electrode delivers electrical current to the surgical site. The current is concentrated in a small area providing high current density to induce heating and thermal tissue damage.^{5,6} A return electrode attached to the patient's body then collects and disperses this current at a reduced current density that does not induce tissue heating.

Electrocoagulation is the process whereby tissue undergoes thermal denaturation through the heating of tissue below its boiling point.⁶ Additional slow heating vaporizes the water content in the coagulated tissue causing tissue drying, also known as desiccation. As superficial coagulated tissues dry out (desiccate), they become less electrically conductive, thereby preventing current from flowing and heating deeper tissue and thereby limiting the depth of coagulation.

In electrosection, tissue adjacent to the electrode is rapidly increased in temperature above its boiling point. This causes a rapid explosive

vaporization of the water content in the targeted tissue coupled with tissue fragmentation. This tissue fragmentation permits the electrode to pass through the tissue and function as a cutting instrument.⁷⁻⁹

A range of electrosurgical devices are available for dermatologic surgery. These range from simple desiccator units (Fig. 16-3) to high-powered operating room ready multifunction devices (Fig. 16-4).

Figure 16-3. A simple electrodesiccation unit. This device is appropriate for almost any dermatologic surgery application.

Figure 16-4. A high-powered electrocautery unit.

ELECTROCAUTERY MODALITIES

Electrosection

Electrosection is the cutting of tissue with current rather than a scalpel. The goal in electrosection is for the cutting of tissue to be brisk, with the lowest effective power setting.^{8,9} If the power is too low, the cutting process will be slow, resulting in a prolonged contact time with greater heating of the incision walls and therefore higher collateral tissue damage. In order to determine the correct output power for a clean incision, start low and increase the power until the maximum cutting speed is achieved. If the power is insufficient, the electrode will not easily glide through the tissue but rather will “stick.”¹⁰ If there is arcing or sparking across the tissue surface, the voltage is too high and needs to be reduced. Once the optimal power setting is determined, the same setting can be used for all subsequent patients with only mild fine-tuning required.

Electrosection is infrequently used in dermatologic surgery due to histologic distortion and a lack of evidence that it is superior to scalpel-based surgery. Electrosurgery causes greater collateral tissue damage, and therefore histologic distortion of surgical margins, compared to scalpel surgery. Thermal damage causes carbonization at the excision margin, collagen denaturation, and vessel thrombosis.^{11,12} It can cause vacuolar degeneration, along with shriveled and shrunken cell outlines with

condensation and elongation of the nuclei and fusion of cells into structureless, homogenized masses with a hyalinized appearance.¹³ All of these factors may result in false positives due to normal structures mimicking tumor.¹⁴ Therefore, when electrosection is used in the context of dermatologic surgery, it is usually performed as a wide undermining technique for large excisions.

When electrosection units first came to market, reports of impaired wound healing and increased postoperative infection rates discouraged their adoption by dermatologic surgeons. As such, there is very little data comparing electrosection to conventional scalpel surgery with respect to incisional speed, postoperative pain and infection, wound healing, or scar cosmesis. The few randomized control trials that do exist are found in the general surgery literature. Not surprisingly, electrosection is associated with significantly less blood loss and shorter incisional time, though it is unclear whether it is associated with any statistically significant difference in postoperative pain, infection, wound healing, or scar cosmesis.^{15,16}

Electrocoagulation

Electrocoagulation can be performed in two manners: contact mode or spray (fulguration) mode. In contact mode, the depth of coagulation is proportional to the size of the electrode tip and its associated power (Table 20-2).

Table 16-2. Factors Affecting Depth of Coagulation

Size of the electrode tip
Power setting
Duration the electrode is in contact with the tissue

For superficial coagulation of small areas (i.e., destruction of small seborrheic keratoses or warts), a fine-tipped electrode should be used. The fine tip concentrates the current to a fine point, allowing the surgeon to use lower power. When using a fine-tipped electrode, the current density in the tissue rapidly decreases with the increasing distance from the electrode. As a result, heat generation is confined to the narrow vicinity of the electrode tip,

allowing targeted heating of the superficial lesion while decreasing the chance of dermal heating, damage, and subsequent scarring.¹⁴

For deeper coagulation, a large-tipped electrode (i.e., a ball- or disc-shaped electrode) and higher power should be used. A large-tipped electrode is effective for deep coagulation but not superficial coagulation because unlike with a fine-tipped electrode, where current density rapidly decreases with the increasing distance from the electrode, current density slowly decreases with the distance, and thus a larger and deeper area is heated. Large-tipped electrodes are, therefore, only indicated for deep coagulation (i.e., destruction of deep reticular dermis after curettage in the setting of destruction of a nonmelanoma skin cancer).

Electrofulguration

Electrofulguration is useful in the setting of coagulation of large superficial areas (i.e., to destroy a large seborrheic keratosis or achieve hemostasis in an oozing field). In electrofulguration, the active electrode is held a few millimeters above the tissue. A spark, or arc of electricity, then jumps from the electrode to the tissue where it moves rapidly from location to location. Unlike using the contact mode, the current is therefore spread superficially over an area larger than just the tip of the electrode.¹⁷

In electrofulguration, each spark acts like an exquisitely fine electrode. The spark itself is high temperature, so it induces tissue destruction and coagulation at the site of contact. However, the temperature rapidly decreases with the increasing distance from the spark itself. Consequently, tissue charring is restricted to superficial tissue. If one wishes to achieve deeper heating and coagulation, this can be achieved by keeping a fulgurating electrode over a confined area for a prolonged period of time. Continuous heating of the superficial layers causes heating of the deeper layers.

Electrodesiccation

During electrocoagulation, especially when performed slowly, the more superficial tissues may dry out. This is called desiccation. This step is important because the current may decrease or stop flowing entirely, limiting the maximum depth of coagulation. When this occurs, a popping sound or

sparkling may occur through the dried nonconductive layer, exploding and fragmenting the dried layer. Desiccation is not guaranteed, does not always happen, and the time to onset is unpredictable. The timing at which desiccation occurs during the course of coagulation is dependent upon the rate of increase in temperature. This is determined by current density. A low current density can allow for a deeper coagulation before the onset of desiccation.⁶ Therefore, in the setting of deep coagulation (i.e., after curettage of a malignant lesion), a low power should be used. With no published data, a rule of thumb is to choose a power which can provide desiccation (popping sound) after 4 to 7 seconds to achieve relatively deep destruction.

There are three factors that influence the depth of coagulation: the size of the electrode tip, the power setting, and the length of time for which the electrode is in contact with the tissue. The longer the electrode is in contact with the tissue, the more heat is generated and the wider and deeper the tissue damage.

Utilizing a lower power with a longer contact duration is not preferable to adopting a higher power with longer contact duration. Longer contact time conducts more heat, leading to increased collateral tissue damage before the desired outcome is attained.^{18–20} This is much the same concept as when choosing pulse duration for a laser. Therefore, to minimize collateral tissue damage, the contact time should be minimized or divided into multiple pulses to allow the tissue to cool between pulses.

Bipolar versus monopolar electrosurgery

The prefixes monopolar and bipolar refer simply to the number of *active electrodes*. In monopolar electrosurgery, an active electrode transfers current to the tissue where it spreads throughout the body before being collected and returned to the electrosurgery unit by a dispersive (return or indifferent) electrode. Often the dispersive electrode is a plate that the patient either grips or is otherwise in contact with. In bipolar electrosurgery, the active electrode is a pair of forceps. Electrical current flows from the active prong through the grasped tissue and into the dispersive (return) prong where it flows back to the electrical generator. Bipolar electrosurgery may be safer

for the patient, since there is less damage to the surrounding tissue and lower risk of distant site burns when compared to monopolar electrosurgery.^{21,22}

Biterminal versus monoterminal electrosurgery

The prefixes monoterminal and biterminal refer to the number of *electrodes in contact with the patient's body*. Bipolar electrosurgery is always biterminal, whereas monopolar electrosurgery may be monoterminal or biterminal.

In monoterminal electrosurgery, there is no dispersive electrode connected to the patient's body. Instead, the return electrode is connected to the earth, often through the power supply cable. These are known as earth-referenced units. These monoterminal units are ubiquitous in medical dermatology suites. However, it is important to note that if an electrically conductive object, such as a metal table or electrocardiogram electrode, makes contact with the patient's body, some current may pass through this object on its return pathway to the ground. If the contact area is small, the current may be concentrated enough to cause a focal burn at the site. Therefore, these devices should only be used on conscious patients who are able to alert the surgeon to such complications, and on insulated tables with no exposed metal parts near the patient's body.

The most common electrosurgical unit used in operating rooms today is a floating or isolated biterminal unit. Unlike earth-referenced units, the dispersive electrode is isolated from earth. Therefore, current will only flow if there is a dispersive electrode attached to the patient.²³ As a result, if the patient comes in contact with a conductive environmental object, minimal to no current will pass through that object, and therefore the risk for burning is minimal. Additionally, the surgeon is protected, since one can touch the active electrode and as long as they do not touch the patient or the dispersive electrode, there is no risk of the surgeon sustaining a burn.

RISKS AND CAUTIONS

Electrosurgery in the setting of cutaneous surgery is very safe, but it is still not without risk. These risks include burns, infection, ocular injury, and cardiac pacemaker, defibrillator, or deep-brain stimulator malfunction.

Electrical burns

Electrical burns occur when high current density flows through a small surface area. This usually happens when there is faulty application of the indifferent electrode, the patient makes contact with a metal surface, or there is current channeling to a distant site.

Improper placement of the indifferent electrode includes placing it over a bony prominence, scar tissue, or metal implants, or when too small of a surface area of the indifferent electrode is in contact with the patient. Current becomes concentrated in this small surface area, resulting in high current density. If this high current density is allowed to continue for too long, then an electrical burn occurs. A patient would normally experience pain and discomfort prior to experiencing a focal burn, but if the area is anesthetized they may not.^{6,23–25}

A patient is also at risk for burns if he or she makes contact with a grounded metal object while electrocautery is occurring. This is especially true when the indifferent electrode is broken or improperly placed, or when using a monoterminal unit. This is because current seeks any alternative low-resistance pathway from the patient to the ground.

Another cause of burns is a phenomenon known as current channeling. This is when current is concentrated as it flows through a small area. For instance, if applying current to a mass with a narrow base or stalk, such as a fibroepithelial polyp, as the current flows into the narrow stalk it is concentrated. This concentrated current can cause a burn at the site of the base of the lesion.^{26,27}

The threat of burns can be mitigated through a few simple precautions. Never leave an active electrode on a patient when not in use. A patient should always be in contact with at least 20 square inches of the indifferent electrode to ensure sufficient current dispersion. This is made easier by flexible indifferent electrodes that conform to the body, the use of protective interface gels, and contact quality monitors. Many modern electrosurgery units have a contact quality monitor for the dispersive electrode. It measures the quality of contact between the patient's skin and the dispersive electrode as well as between the electrode and the generator. However, there is no clinical evidence to support the notion that a contact quality monitor minimizes the risk of burns.¹⁰

Never use a bent indifferent electrode, as this can create a sharp point that concentrates current. Make sure the patient is not in contact with any metal surfaces. If the patient has any metal in his body, the dispersive pad should be placed between the metal and the surgical site to prevent current from passing through the patient's implanted device. When treating a pedunculated lesion for which there is risk of channeling, use bipolar forceps or wrap a saline-soaked sponge (an electrolyte conductor) around the stalk.²⁶⁻²⁸

Infection risk

In experimental settings, electrodesiccation has been associated with transmission of human papillomavirus (HPV), hepatitis B virus, and *Staphylococcus aureus*. Some people erroneously think that the heat induced by electrocoagulation sterilizes the electrode tip. This is true in electrocautery where heat is generated in the tip but not in electrocoagulation where heat is only produced in the tissue. Special precautions in the form of facial masks, protective eye wear, and a smoke evacuator should be used when treating HPV-related lesions, since HPV can become aerosolized in blood micro-droplets and in electrosurgical smoke posing a risk to the patient, physician, and surgical staff (Fig. 16-5).²⁹⁻³¹

Figure 16-5. Smoke evacuation systems are a useful adjunct to electrosurgery.

Eye injury

When operating in the periorbital area, patients should wear nonmetallic corneal shields, since sparks may arc toward the globe causing corneal damage and scarring. The corneal shields must be plastic rather than metal to prevent conducting the current toward the globe.³²

Cardiac pacemaker, defibrillator, or deep-brain stimulator malfunction

Electrosurgery has the potential to interfere with cardiac pacemaker, implantable cardioverter–defibrillator (ICD), or deep-brain stimulator function. Pacemakers are generally classified as fixed rate or demand type. Fixed-rate pacemakers fire at a predetermined rate irrespective of the

intrinsic cardiac rhythm. Demand-type pacemakers fire at a predetermined rate only in the absence of intrinsic cardiac rhythm. Demand-type pacemakers are further subdivided into ventricular inhibited or ventricular triggered. The ventricular-inhibited, demand-type pacemaker is the most common pacemaker in the United States.

Since fixed-rate pacemakers fire at a fixed rate regardless of intrinsic cardiac rhythm, they lack sensing circuitry. Consequently, exogenous electrical signals from the active electrode pose no threat to the patient. Conversely, all demand pacemakers contain sensing circuitry and are therefore susceptible to interference from extraneous electrical current. The function of demand pacemakers is to prevent bradycardia and asystole. The ventricular-inhibited pacemakers do this by firing when the patient's intrinsic cardiac rhythm is slower than the preset rate. A ventricular-triggered device fires with each spontaneous heartbeat as well as at a predetermined rate in the absence of intrinsic rhythm.^{28,33}

The electromagnetic output of electrosurgery can interfere with the sensing circuitry of demand pacemakers causing them to erroneously perceive the electrical current from electrosurgery as spontaneous ventricular contraction. In the setting of a ventricular-inhibited pacemaker, the pacemaker perceives this electrical current as a spontaneous heartbeat and erroneously enters stand-by mode. This can cause bradycardia and asystole leading to syncope, seizure, or death. In a ventricular-triggered device, the electrical current is misread as a spontaneous heartbeat causing the pacer to falsely stimulate ventricular contraction. This can cause life-threatening tachyarrhythmias or ventricular fibrillation. Although any electrosurgical procedure poses a risk for pacemaker-related complications, electrosection poses the highest risk.^{31,33}

An ICD is a device that sends a defibrillatory shock to the heart if it senses tachyarrhythmia or ventricular fibrillation. It is usually inserted into an abdominal or infraclavicular subcutaneous pocket. Electrosurgery can cause an ICD to erroneously shock the heart, which is not only excruciatingly painful to an alert patient but can induce life-threatening tachyarrhythmias. Electrosurgery can also damage the ICD device itself.³¹

A deep-brain stimulator is an implanted device that generates electrical impulses to control movement disorders such as essential tremor or Parkinson's disease. An electrode implanted in the brain is connected to a

pulse generator that sits in a subcutaneous pocket in the chest, much like an ICD. As with an ICD, electrosurgery can interfere with functioning of the brain stimulator.

Electrosurgery in the setting of pacemakers, ICDs, or deep-brain stimulators poses life-threatening complications, but how common are they? A survey study of 166 Mohs surgeons with a total of 1959 years of experience examined the number and type of complications due to electrosurgery. The incidence of interference was exquisitely low with 1.6 cases/100 years of surgical practice. The incidence of clinical adverse events was even lower at 0.8 cases/100 years of surgical experience. There was no significant morbidity or mortality. The 25 cases of interference were broken down as such: 8 patients experienced skipped beats, 6 patients had spontaneous reprogramming of their pacemaker, 4 patients had their ICD fire, 1 patient had a shortening of his pacer's battery life, and 1 patient experienced tachyarrhythmia. Of these 25 cases, 18 of the patients experienced a clinical adverse outcome: 6 had syncope, 5 had altered sensorium, 3 experienced palpitations, 3 required an outpatient cardiology consult, and 1 experienced hemodynamic instability.²⁹ There are only two reports of deep-brain stimulator interference.³⁴

Despite this data, several groups, including the American Society of Anesthesiologists, recommend that the patient's cardiologist be consulted prior to using monoterminal electrosurgery, and that devices be interrogated within a month after any monoterminal electrosurgical procedure, though the degree to which these suggestions are followed is unknown.³⁵

Still, the use of electrosurgery in patients with implanted devices is very safe. This is in part due to the fact that modern-day pacemakers are designed with metallic covers and filters to protect the device from external electrical interference, and therefore minimize the risk of malfunction. However, precautions should still be taken. Place the grounding electrode at a site far from the heart and pacemaker and try to avoid having the heart lie directly in the path between the treatment and indifferent electrode. Keep electrosurgical current bursts to less than 5 seconds. If operating near a pacemaker or ICD, utilizing electrocautery or biterminal forceps will avoid or minimize current leakage in the patient. Similar precautions should be taken with patients who have cochlear implants.

Persistent bleeding

While electrosurgery is well suited to the cauterization of small blood vessels, larger vessels, and even some smaller arterial vessels, may not respond definitively to electrosurgical approaches. This may be immediately obvious, as when persistent bleeding remains even after repeated attempts at electrocoagulation; more insidiously, some larger vessels will initially appear to be effectively treated with electrosurgical approaches only to persist in bleeding in the postoperative period. Therefore, less-experienced dermatologic surgeons should err on the side of ligating larger vessels. This may be accomplished in a number of ways; see [Chapter 13](#) for a detailed discussion of suturing techniques for vessel ligation.

ELECTROSURGERY FOR REASONS OTHER THAN HEMOSTASIS

Electrosurgery and hair removal

There are two mechanisms by which hair removal can be achieved through electrosurgery: electrolysis and thermolysis. In electrolysis, a needle electrode is placed into the hair follicle and a direct electrical current (galvanic current) is then applied resulting in a chemical reaction that destroys the hair follicle. In thermolysis, alternating current is applied and the hair follicle is destroyed through thermal damage. Thermolysis is faster than electrolysis, though there is a greater risk of damage to the dermis and ensuing scar formation.^{36–38} These are time consuming but are effective methods of hair removal for nonpigmented hairs or in patients with pigmented skin.

Electrosurgery for the treatment of malignant skin lesions

Electrodesiccation and curettage (ED&C) is a common and effective treatment for benign and superficially invasive neoplasms.^{39–41} In the right setting, it is quick with less morbidity and cost than surgical excision. It

involves two to three cycles of curettage followed by electrodesiccation. The ideal scenario for ED&C is a broad, superficial lesion in an area with thick underlying dermis, that is, the trunk or extremities. ED&C is not an ideal treatment modality for lesions that have the potential for follicular extension, as they are at higher risk for recurrence.^{1,42–47}

Basal cell carcinoma is perhaps the most common neoplasm treated by ED&C. Recurrent or micronodular/morpheaform basal cell carcinomas should be treated surgically through excision rather than ED&C because they are at increased risk for having deep dermal infiltration. The cure rates with ED&C are highly operator dependent, with cure rates ranging from 88% to 99%. The studies that report the highest cure rates also utilize the largest reported safety margins, ranging from 2 to 8 mm.⁴⁷ A meta-analysis of basal cell carcinomas treated by ED&C reported a weighted average 5-year recurrence rate of 8%.⁴⁸

One study examined the determinants of 5-year recurrence rates of 2314 primary basal cell carcinomas treated by ED&C between 1955 and 1982. The only variables that impacted occurrence rate were lesion size and location. Patient age, sex, or duration of the lesion had no impact. Researchers divided the body into three categories: high-, middle-, or low-risk anatomic sites. The high-risk sites included the nose, paranasal, nasolabial fold, ear, chin, mandibular, perioral, and periocular areas. Middle-risk sites were the scalp, forehead, pre- and postauricular, and malar areas. Low-risk sites were the neck, trunk, and extremities. Lesions that were ED&C'd in low-risk areas had a 3% recurrence rate within 5 years regardless of the lesion's diameter. Middle-risk sites had a 5-year recurrence of 5% for lesions <10 mm in diameter and a 23% risk for recurrence with lesions >10 mm. High-risk sites had a 5-year recurrence rate of 5% for lesions <5 mm and 18% for lesions >6 mm.⁴⁹

Step-by-Step Approaches

Hemostasis with monopolar electrocautery

1. Defer hemostasis until the lesion is completely excised and appropriately undermined.

2. In order to achieve complete hemostasis, visualization of the wound bed and undermined surface should be achieved via skin hooks and ample gauze.
3. For electrocoagulation to work effectively, the operative field must be dry, as blood diffuses the current flowing from the electrode. A dry field is best achieved utilizing a two-handed technique. With the nondominant hand, use forceps and a piece of gauze to dry the field and visualize the source of bleeding. With the dominant hand, cauterize the source of bleeding with the active electrode. If possible, an assistant should hold gauze at the dependent area of the wound to absorb any dripping blood.
4. It is easiest to achieve hemostasis by operating in the direction of gravity. For instance, if operating on the neck, work from the superior to the inferior pole.

Achieving hemostasis with bipolar electrocautery

1. Dry the field to visualize the sites that are bleeding.
2. Clamp the tines of the bipolar electrode, shut and touch it to the areas that are bleeding.

Achieving hemostasis of a bleeding vessel

1. Use gauze to dry the field and visualize the bleeding vessel.
2. Using fine-toothed forceps or a hemostat, grip the vessel, then touch the active electrode to the forceps or hemostat and apply monopolar current through it.
3. If using a bipolar electrode, simply grip the vessel between the two tines and apply current.
4. If a popping sound is heard or a spark is seen, current flow should be stopped and the area re-evaluated to ensure satisfactory hemostasis. In order to optimize hemostasis, the surgical field should be dry, as blood will diffuse the current flowing from the electrode.
5. Only small vessels should be cauterized in this fashion; larger or arterial vessels would benefit from direct suture ligation.

How to perform electrodesiccation & curettage

1. Anesthetize the area with a mixture of 1% lidocaine with epinephrine.
2. With the sharp end of the curette pointing down toward the skin, scrape the affected area to the base, which can be identified by the gritty sensation of the dermis. In the setting of a skin cancer, the cancerous area is more friable compared to normal skin.
3. Dry the base with gauze, then fully electrodesiccate the base with electrosurgery.
4. Recurette the base in a different direction and once again desiccate the base. Repeat for a total of three passes.

Another consideration to take into account when deciding upon whether or not to treat a lesion by ED&C is cosmesis. On the trunk and extremities, ED&C most often results in residual dyspigmented patches, though atrophic, hypertrophic, or keloidal scars can occur. On the face, ED&C often produces a fine white macule or patch, while indurated or depressed circular scars are a risk. For many patients, ED&C offers a cosmetically acceptable scar.^{47,49}

Electrosurgery for the treatment of benign epidermal lesions

Benign skin lesions such as seborrheic keratoses or warts can be treated with superficial coagulation by using a fine-tip electrode or electrofulguration with very low power. After a quick, gentle treatment, the lesion should be wiped off. If there is any residual lesion left, a subsequent pass of superficial electrocoagulation can be performed. If there is spark formation, this is an indicator of deeper injury. This can be avoided by reducing the voltage, power, or contact time.

CONCLUSIONS

Electrosurgery is a universal staple of the dermatologic surgery practice, whether used for hemostasis, treatment of nonmelanoma skin cancer, or benign lesion desiccation. A comprehensive appreciation of the underlying principles behind electrosurgery helps the dermatologic surgeon better decide on optimal techniques and approaches for a variety of applications.

CHAPTER 17 Incision and Drainage

Sirunya Silapunt
Michael R. Migden

SUMMARY

- I&D may be used to treat various conditions that require the release of enclosed contents, such as hematomas, furuncles, and infected cysts.
- Placing the incision parallel to relaxed skin tension lines may mitigate the appearance of more prominent scars.

- While these procedures are straightforward and can be performed with great rapidity, a poorly performed I&D procedure may serve only to exacerbate an already unpleasant or even dangerous condition.

Beginner Tips

- Choose the most fluctuant area of the lesion, which represents the most liquefied portion of exudate, for easily drainage.
- Choosing the dependent area to facilitate drainage by gravity effect may also reduce the need for manual pressure and attendant patient discomfort.
- Thicker exudate such as blood, coagulum, or mucin requires a longer time to start draining.

Expert Tips

- An 18G needle can be useful for I&D on very small lesions. Due to the small opening of this type of incision, thick exudate may not drain out easily. After stabbing, keep the tip of the 18G inside the lesion, push the needle tip laterally to widen the slit-like cut, and wait for exudate to drain.

- Collect fresh, uncontaminated exudate for swab culture to improve the accuracy of culture and sensitivity; avoid collecting the skin surface–contaminated exudate. Allow the exudate to be collected to drain without running on the skin by compressing the lesion and holding the tip of the swab at the proper position and angle.

Don't Forget!

- If no or minimal drainage occurs, assess the patency of the incision site.
- Inject lidocaine in the superficial dermis, not into the lesional cavity. Pain with incision may occur when lidocaine injection occurs inside the lesion instead of the dermis and adjacent subcutaneous tissue. A ring block can also be considered.

Pitfalls and Cautions

- The incision should be stopped as soon as the surgeon senses low tissue resistance, in order to avoid tissue damage at the base of lesion.
- Bleeding at incision sites is common. Use external compression to control bleeding.

Patient Education Points

- I&D is a fast and effective procedure, but does not guarantee that a given fluid collection will not recur.
- For inflamed or infected cysts, patients should be warned to expect recurrence, and definitive excisional surgery may be needed in the future.
- I&D requires significant postoperative care, as wounds generally need to be packed or cared for in other ways. Patients should understand that postprocedure management is a process, and drainage may persist for longer than anticipated.

Billing Pearls

- I&D of an abscess is most frequently coded using CPT code 10060. When draining multiple abscesses, 10061 may be coded, and this code may be used for “complicated” lesions as well, though its use should clearly be justified in the body of the surgical report. Additionally, 10140 may be used for nonabscess I&D. The 10160 code may be more appropriate when performing I&D using an 18G needle alone.

CHAPTER 17 Incision and Drainage

INTRODUCTION

Incision and drainage (I&D) is commonly performed in both general and procedural dermatology outpatient settings. This approach may be utilized to treat various conditions that require the release of enclosed contents, such as hematomas, furuncles, infected cysts, and collections of other extraneous substances. While the advantage of I&D is that it is easy to perform, patients should be warned regarding the requirement of postprocedural care. Moreover, since expression of the entire cyst wall is rarely effected when treating inflamed or infected cysts, recurrence of such lesions may be seen (Tables 17-1 and 17-2).

Table 17-1. Indications for Incision and Drainage

Hematoma
Carbuncle or furuncle with fluctuance
Acute paronychia with abscess
Inflamed epidermal inclusion cyst
Dissecting cellulitis with exudate collection
Hidradenitis suppurativa with abscess
Pseudocyst of the auricle
Acne cyst
Digital mucous cyst
Mucocele
Seroma postsurgery
Trapped blood coagulum from sclerotherapy

Table 17-2. Advantages of Incision and Drainage

Evacuates the infectious material containing the pathogen
Enhances antibiotic diffusion into the local tissue improving their efficacy after release of buildup pus or exudate
Removes accumulated blood, which may act as a nutritional source for bacterial infection
May enable visualization of the bleeding site in active hematoma
Facilitates specimen collection for culture and sensitivity
Decreases inflammation associated with accumulation of inflammatory exudate
Opens and collapses the pocket space, minimizing recollection of the exudate; promoting healing (fibrosis)
Rapidly decreases the size of lesions improving their appearance; easing cosmetic concerns

There are no absolute contraindications for I&D. Abscesses of the palms and soles can be associated with complications, and may require

consultation with an appropriate surgical specialist. In select cases, I&D may be best performed in an operating room with conscious sedation. These include extremely large abscesses, complicated skin and soft tissue infection involving deeper invasion of tissue, or deep abscesses in areas that are difficult to anesthetize.

Patient education and evaluation

Patient evaluation should include inquiry as to history of lidocaine allergy, latex allergy, and hypertrophic scars or keloids. Further, the patient's expectations of the cosmetic outcome should be discussed. Informed consent should be obtained and the patient should be counseled regarding the risks, benefits, and alternatives of the procedure, as well as potential risks of not undergoing the procedure (e.g., acute abscesses). Risks include, but are not limited to, infection (new or worsening of existing infection), bleeding, pain, nerve damage, and scar formation (keloids and hypertrophic scars).

Procedure overview

All equipment should be placed within reach, ideally on a Mayo stand. Adjust the lighting to allow easy visualization of the abscess.

Choose the incision site in the most fluctuant and prominent part of lesion, where the contents appear most liquefied, in order to permit rapid and effective drainage. In addition, consider starting with the most dependent portion of lesion for the ease of drainage utilizing gravity effect. The patient should be properly positioned so that the area for drainage is fully exposed and easily accessible, while ensuring the patient's comfort.

Apply a topical antiseptic (alcohol, povidone–iodine, or chlorhexidine) to the entire lesion and particularly to the area to be incised, followed by application of a sterile drape as indicated. Avoid using chlorhexidine in the ear and periorbital areas.¹

An absorbent pad, gauze, or chuck is placed to protect other areas from draining exudate. Placement of a cotton ball or dental roll inside external ear canal is recommended to protect the ear from draining exudate. Gloves, gown, and a face shield should be worn at all times during the procedure to avoid exposure to bodily fluids, particularly from high-pressure abscesses.

Local anesthesia is injected into the selected incision site and around the lesion to minimize both the tenderness associated with pressure as well as the incision proper. This is achieved with infiltration of 1% to 2% lidocaine with or without epinephrine using a 30G needle. Care should be taken to deliver anesthetic solution into the skin overlying the lesion instead of infiltrating lidocaine into the cavity. Needle insertion is just under and parallel to the surface of the skin, and anesthetic is injected into the intradermal and subcutaneous tissues until blanching of the tissue is noted as the anesthetic diffuses. In patients with lidocaine allergy, alternatives can be employed. For a more detailed discussion of anesthetic choices, see [Chapter 12](#).

Nerve block or local field block may be required for larger and deeper lesions to ensure the patient's comfort. A ring block may permit anesthesia of the entire target area without directly injecting local anesthetic over the fluctuant mass, which may mitigate the risk of spray back. This approach, however, also does not infiltrate any epinephrine into the area to be incised, so an attendant increased risk of mild bleeding may be anticipated. Adequate anesthesia is essential for complete and thorough drainage. Depending on the patient's pain threshold, ice cubes, ethyl chloride spray, or topical anesthesia may be helpful if applied prior to injecting lidocaine to decrease discomfort delivering local anesthesia. This is particularly important as the acidic environment of infected tissue may make it more difficult to achieve sufficient anesthesia with local agents.

When approaching small digital mucous cysts and trapped blood coagulum following sclerotherapy, I&D may be performed by rapid single puncturing with a needle, and local anesthesia may not be needed. Lidocaine injection may blanch the area or otherwise make these lesions more difficult to visualize for I&D. Ice cube, ethyl chloride spray, or topical anesthesia used instead of lidocaine injection may be better for such lesions. Injectable lidocaine is necessary, however, when I&D of a digital mucous cyst is followed by destruction using electrodesiccation.

INCISION

For smaller lesions, a #11 surgical blade is used to incise the selected and anesthetized area. It is commonly used for I&D due to its sharply pointed tip

which is well suited for a perpendicular stabbing approach into the lesion, though if unavailable any blade, such as a #15 scalpel blade, will suffice. Following the initial stab to enter the cavity, the incision is extended to create an opening large enough for drainage, which is dependent on the consistency of exudate, and to prevent recurrence of lesion (recollection). For lesions of larger size and in certain locations (e.g., deeper set lesions on the back), a #15 or #10 surgical blade may be utilized preferentially.

Placing the incision parallel to relaxed skin tension lines may mitigate the appearance of more prominent scars. Care should be taken that the incision length not to be too short, restricting the ability of exudate to adequately drain, though an unnecessarily long incision will yield a more prominent scar. Err on the side of creating a shorter incision, as this can always be enlarged if needed.

Care should be taken not to overextend the depth of initial puncture incision, as accidentally stabbing through the base of the lesion's cavity may sever underlying tissue or vessels, increasing the risk of persistent infection or bleeding.² Stab incision depth should be designed only to permit the tip of surgical blade to pass through the skin and the wall of lesion; generally, once this is accomplished, there will be an immediate drop in tissue resistance, and often some of the material to be drained will appear.

Sterile cotton-tipped applicators may be inserted to gently probe the cavity down to its base and facilitate the removal of any remaining loculated or congealed fluid. Special care should be taken in making the incision if there are prominent vessels or nerves in the area, or when working close to anatomic danger zones. When incision is performed on highly vascularized area, such as a mucocele on mucosal lip, consider having an assistant apply steady pressure around the lesion while performing I&D for bleeding control and improve visualization. Care should be taken when incising high-pressure lesions, as the contents may escape explosively in a projectile manner, contaminating the surgeon and surrounding area.

Alternative approaches

Direct puncture with an 18G needle may be used in small lesions that have relatively nonviscous contents, given the relatively large bore size of the 18G needle. Contents of a digital mucous cyst or trapped blood coagulum can be

adequately drained when the tip of the 18G needle is kept inside the target space and pushed laterally away from the wound access point in order to open and enlarge the defect. The resulting rounded opening generally permits spontaneous drainage of the exudate. Care should be taken not to remove the needle immediately after puncture so that the nascent skin access point does not reclose. Patience is required with this approach, as it may require 1 to 2 minutes to see the viscous contents slowly drain out while the tip of the needle is kept in place. Importantly, the contents will not rapidly and spontaneously drain. A cotton-tipped applicator is useful to push the lateral wall of lesion outward immediately after the needle is removed to facilitate complete drainage. I&D of digital mucous cysts may be followed by other treatments such as cryotherapy or injection of sclerosing solution or triamcinolone.^{3,4}

Direct puncture with an 18G needle connected to a syringe followed by negative pressure application by withdrawing the syringe plunger can be used to drain the exudate associated with dissecting cellulitis or trapped blood coagulum of larger veins. The use of duplex ultrasound guidance is particularly helpful in avoiding local arterial injury.

Performing the incision with a punch instrument can be useful because it gives a round-shaped opening for drainage instead of a linear slit. Due to the round-shaped opening, exudate continues to drain at home after the performance of in-office I&D, which may minimize the need to insert wound-packing material. Punch incision is particularly useful in draining thick exudate such as noninflamed epidermal inclusion cysts, as releasing the keratinous content alleviates discomfort from built-up pressure.⁵ The size of the punch instrument should be commensurate with the size of lesion and the thickness of exudate. However, the greater ease of drainage associated with utilizing a larger-sized punch instrument should be weighed against the risk of a more substantial postoperative scar. In general, a punch instrument size of 4 mm or less should produce acceptable scar cosmesis.⁶

DRAINAGE

Initially, the exudate may spontaneously drain after incision is performed secondary to built-up pressure. When the lesion is incised at the most fluctuant and dependent area, thin exudate will spontaneously drain out

without the need to apply pressure to the lesion, as long as the incised area remains patent.

External pressure may be required in order to definitively drain the remaining exudate, though this may be at the expense of patient comfort. To minimize pain, it is important to apply pressure to the lesion carefully, though often the relief associated with internal pressure reduction outweighs any transient pain associated with the placement of lateral pressure. Pressure is applied gently and slowly from the lateral sides of the lesion toward the incision site (Figs. 17-1 to 17-5). Applying pressure from the top of the lesion at the incision site down to the bottom of the lesion may not result in effective drainage; indeed, the contents may move laterally toward the wall of the fluctuant mass when pressure is applied vertically, and this approach should therefore be avoided. For smaller masses, using a cotton-tipped applicator provides a better focal point of pressure than using a fingertip, which is much larger. If the patient experiences significant discomfort, additional injections of local anesthetic, possibly as a ring block, may be beneficial.

Figure 17-1. I&D on the most dependent portion of a cyst on a patient's cheek in supine position utilizing gravity effect for the ease of drainage. Note that lateral pressure (*left*) results in the extrusion of the contents, while downward pressure (*right*) does not.

Figure 17-2. Pressure is applied gently and slowly from the lateral side of lesion toward the incision site, which moves the contents toward the exit provided by the incision. The contents may move laterally toward the wall of lesion and away from the exit when pressure is applied vertically.

Figure 17-3. A small stab incision is made at the inferior pole of the abscess.

Figure 17-4. Gentle lateral pressure is used initially to ensure that contents are effectively extruding through the incision.

Figure 17-5. Firm lateral and upward pressure is applied to force the expulsion of all cyst contents.

Curved hemostats may be used to enlarge the opening from a narrow slit-like space to a wider exit point, which is especially helpful for thick purulent

exudate. The closed tips of curved hemostat clamps are inserted into the incised area and then opened to widen the incised area. The nondominant hand is used to apply pressure to further drain the contents. Hemostats may also be used for careful blunt dissection to break up loculations and facilitate further drainage. Forceps can be used to open the exit for drainage, though they provide only minimal leverage. Care should be taken not to overly stretch and traumatize the skin edges with hemostats or forceps, as this may affect the healing and ultimate cosmesis of the incision site.

When I&D is performed on an acute hematoma, its solidity requires a larger incision and external pressure to remove the clot. Older blood collections can be drained with a shorter incision length or an 18G needle. Attention should be paid to any fresh red blood when I&D is performed on hematoma, which may indicate active bleeding that would need to be definitively surgically addressed.

For acute paronychia with an abscess located immediately adjacent to the nail sulcus, the tip of a #11 or #15 surgical blade or 21G or 23G needle may be gently inserted underneath the proximal or lateral nail folds to create an opening for drainage.^{7,8} Gentle pressure is applied to extrude the purulent exudate. Care should be taken to point the sharp edge away from the nail, and not to insert it too aggressively in order to avoid damaging neurovascular bundles, tendons, or the nail matrix. A piece of gauze may be placed underneath the nail fold to allow continued drainage.⁹ For an abscess not located immediately adjacent to the nail sulcus, incision is made directly over the abscess and/or in line with the lateral nail fold to decompress the abscess.¹⁰

If indicated, swab culture and sensitivities may be sent out using freshly drained exudate. Avoid contacting the tip of swab with skin or mucosal surface to prevent contamination by normal flora. A sterile syringe may be used to obtain a sample from the interior aspect of the cavity.

Irrigation may be performed to further remove the infectious or inflammatory exudate. The tip of a sterile, normal saline-filled syringe is inserted through the incised wound, and the cavity is gently rinsed to thoroughly irrigate the cavity until the effluent is clear. Copious quantities of gauze or absorbent pads should be placed at the site to absorb fluid and minimize splash-back over the surrounding area and operator. The nondominant hand may be used to apply gauze to cover the incised area

during irrigation. A syringe with a built-in splash shield may also be used. An appropriate incision size will enhance irrigation and prevent excessive buildup of pressure within the lesion.

If further drainage is required, wound-packing material, such as 1/4- or 1/2-inch packing strips with or without iodoform, is gently inserted through the incision site and loosely packed inside the lesional cavity using hemostats or forceps. This will prevent premature closure of the incised wound, which can lead to recollection. Care should be taken to avoid overpacking the wound, which could cause ischemia of the surrounding tissues and impede the desired drainage.¹¹

Electrodesiccation may be performed after I&D of mucoceles or digital mucous cysts to close the dead space and avoid recollection of the exudate.¹² Any active bleeding points are cauterized.

A pressure dressing may be needed on some lesions in order to collapse the cavity, minimize recollection of exudate, and minimize dead space, which could lead to reaccumulation. Dissecting cellulitis of the scalp requires pressure dressings and head wraps, as the exudate can rapidly reaccumulate. This pressure dressing may also serve to help control bleeding.

Postprocedure care

Counsel the patient on local wound care. Change the wound dressing and/or packing every 24 hours and after each shower. Petrolatum may be applied to an incised wound that does not require further drainage in order to promote wound healing.

Cover the wound with a sterile, nonadherent dressing. Apply several layers of gauze to absorb any persistent drainage, and secure the dressing with surgical tape such as paper tape.

A compression dressing may be applied if indicated.

Counsel patients regarding the likelihood of blood- or exudate-saturated gauze being present during dressing changes.

Antibiotics may be indicated for certain diagnoses, such as hematoma or infection. Preoperative treatment with antibiotics may be a helpful adjunct for the I&D of abscesses in patients who are at increased risk for endocarditis.¹³

Analgesic medications may be helpful if indicated. In general, the majority of pain and discomfort should be significantly relieved after pressure is released following I&D.

Recounsel the patient regarding the expected scar formation when the incised wound is allowed to heal by the second intention, particularly with large hematomas. Also, outline the risk of recurrence.

Follow-up may be scheduled within a few days to a week for wound check, dressing change, or packing material removal. Wound-packing material is removed when no fresh exudate is visible, and a simple dressing with gauze is then sufficient.

Instruct the patient to call and/or return before the scheduled appointment if there are any signs of worsening or infection such as redness, swelling, tenderness, or fever.

Risks of I&D and their management

The potential complications of I&D include inadequate drainage, infection, bleeding, nerve damage, hypertrophic scars, and keloids. Methods to manage these complications are summarized below.

Inadequate drainage

The drainage exit may close off too soon, resulting in inadequate drainage. This can be prevented by using wound-packing material or a punch incision technique, or by leaving a cotton-tipped applicator in place during drainage.

Infections

While abscess is one of the most frequently seen indications to perform I&D, local infection can occur in noninfectious indications of I&D as a result of the procedure itself. Purulent drainage, swelling, persistent redness, and delayed healing may be evident, and when these are noted, the patient should undergo evaluation and treatment. Management of these infections includes an appropriate topical and/or systemic antibiotic, daily wound care, and repeat I&D, if the site develops an abscess with fluctuance. Responsible organisms vary by anatomic location, though *Staphylococcus aureus* is most commonly seen.

Bleeding

Bleeding is managed by external compression. Appropriate use of hemostatic measures is essential at the site of incision as well as for obtaining adequate hemostasis within an active hematoma requiring I&D.

Hypertrophic scars or keloid formation

Hypertrophic scars may be treated with intralesional corticosteroids, pulsed-dye laser, silicone gel sheeting, cryotherapy, or a combination of these methods.¹⁴ For keloids, these treatments may be combined with surgical excision, intralesional 5-fluorouracil, intralesional interferon, external compression, or a combination of these methods.^{14–17}

Nerve, tendon, or ligament damage

Paresthesia may occur at the incision site; this should improve with time. Motor nerve damage is extremely rare. A severed tendon or ligament requires referral to the appropriate specialties for evaluation and repair. The risk of this occurring is mitigated by remaining at the appropriate depth during the incision of the lesion. Consider the size and depth of lesion, anatomic location, and length of the sharp utilized as an incising instrument prior to performing the procedure, and a thorough understanding of local anatomy is of vital importance.

CONCLUSIONS

When properly performed, I&D is a useful treatment for abscesses, cysts, hematomas, and numerous other conditions. While these procedures are straightforward and can be performed with great rapidity, a poorly performed I&D procedure may serve only to exacerbate an already unpleasant or even dangerous condition. Therefore, a deep respect for anatomy, as well as an understanding of the appropriate indications and contraindications for this approach, remains of vital importance.

CHAPTER 18 Layered Excisions and Surgical Repairs

Jonathan Kantor

SUMMARY

- Linear closures involve direct side-to-side closure of the surgical wound.
- Layered linear closure remains the gold standard for wound closure given its predictable outcomes, reasonable cost to the patient and healthcare system, and low risk of complications.

- Even very large defects, including those on the face, can often be closed in a linear fashion, as long as aggressive undermining and dog-ear correction are performed.
- A significant advantage of linear closures is their predictability; since outstanding blood flow is maintained to the wound edge, these closures often result in fine-line nearly imperceptible scars when carefully designed and executed.

Beginner Pearls

- Breaking down the excision and linear repair into its component parts helps conceptualize each requisite step.
- Never attempt to rush a step; most shortcuts result in the need for a far more time-consuming correction.

Expert Pearls

- Large defects on the face do not necessarily require flap repair.
- Linear closures have almost no risk of flap loss, and so are particularly useful approaches for closures in tobacco users.

- Using a rhombus or tangent-to-circle closure approach may result in smaller apical angles and less dog-ear formation.

Don't Forget!

- When deciding between a large linear closure and a flap, keep in mind that linear closures have less of a tendency to “burn bridges” for future repairs, an important consideration in the patient with florid skin cancers.
- If a wound closed with buried sutures alone results in significant gaping or overhanging dermis, do not attempt to solve this with superficial suture placement. Instead, remove the excess dermis and/or replace the deep sutures.

Pitfalls and Cautions

- Always carefully identify the source of any oozing and address it directly; judicious use of electrosurgical approaches will help reduce the amount of necrotic tissue left in a wound.
- Gentle tissue handling will result in improved outcomes, decreasing the risk of necrosis and infection.

Patient Education Points

- Explaining that any additional scar length will likely heal with a minimally visible line may go a long way toward patient reassurance.
- Always review the planned degree of eversion with the patient so that there is no confusion or worry in the immediate postoperative period regarding the ridged appearance of the wound.

Billing Pearls

- As a general rule, extensive undermining, dog-ear correction, or other complex steps are needed to bill for a complex closure.
- No amount of undermining shifts a linear excision and repair to a bilateral advancement flap for billing purposes.

CHAPTER 18 Layered Excisions and Surgical Repairs

INTRODUCTION

Direct linear closure of surgical wounds is the primary technique used for defect closure in dermatologic surgery. Linear closure is favored for several reasons, including its ease of execution; reliable and predictable healing pattern; rapidity; and reproducibility. Much of the dermatologic surgery literature has historically focused on novel flap and graft techniques, though recently a renaissance in linear closure design has occurred. Even large or deep defects on the face may be amenable to linear repairs, and indeed this may represent the best option for many such wounds.¹⁻⁷ When feasible, layered linear closure remains the gold standard for wound closure given the predictable outcomes, reasonable cost to the patient and healthcare system, and low risk of complications. Fundamental linear closure techniques, including undermining, hemostasis, tissue handling, and suture placement, represent the bedrock of all surgical closures, from small punch biopsies to large flaps.

NOMENCLATURE

The term “elliptical excision” has been used historically to denote linear wound closures, though numerous authors have, over the years, pointed out that the basic shape used by most dermatologic surgeons for closure design is not, in fact, an ellipse (Fig. 18-1).⁸⁻¹² The term “fusiform excision” has,

therefore, been proposed as an alternative, though it has yet to be universally adopted.

Figure 18-1. The rhombus (tangent to circle) closure inscribed within a fusiform design using a theoretical length-to-width ratio of 3.5:1.

The rhombus, or tangent-to-circle, design is a geometrically efficient approach to linear wound closure. Note that *rhomboid*, however, does not mean rhombus-like, but rather refers a specific geometric shape defined by Euclid as a parallelogram where adjacent sides are of unequal lengths. Therefore, these closures should not, from a Euclidean perspective, be referred to as rhomboid.

Most linear excisions are closed in a layered fashion, with repair of the dermis and/or fascia preceding epidermal approximation. Surgeons may refer to an *intermediate* closure and *complex* closure; these terms relate to the *billing* of closures using CPT code series. As a general rule, extensive undermining, dog-ear correction, or other ostensibly complex steps are needed to bill for a complex closure.

Some surgeons refer to undermined *flaps* of tissue that are *advanced* into the center of a wound in order to close a linear excision. While it is technically appropriate to refer to undermined sections of tissue as skin flaps, no degree of undermining shifts a linear excision and repair to a bilateral advancement flap for billing purposes, as the latter requires a true adjacent tissue transfer (for a detailed discussion of flap dynamics and advancement flaps, see [Chapters 20](#) and [21](#), respectively; for a discussion of billing, see [Chapter 10](#)).

PREOPERATIVE EVALUATION

The preoperative consultation for most linear excisions and closures can safely take place on the day of surgery, and includes a detailed medical and social history, with particular attention to the use of medications or supplements that may affect bleeding as well as tobacco use, which has a marked effect on the postoperative healing process. The details of the preoperative evaluation in general are addressed in [Chapter 3](#).

Patients should understand that there is always more than one way to skin a cat; all surgical procedures present risk, and all surgical procedures have alternatives—including avoiding surgery altogether. It is the balance of risk and benefit that must be addressed with each patient individually.

This individualized approach to patient consent and education should extend to the preoperative evaluation of the planned procedure as well. Thus, the planned surgical site should be carefully assessed visually, palpated, and the range of motion of the planned surgical site and surrounding tissues should be closely assessed. For example, when designing facial repairs the surgeon should sequentially have the patient move through the entire range of motion (frown, smile, grimace) in order to better gauge the relaxed skin tension lines (RSTLs) and the presence of any underlying fibrous attachments. In recent years, there has been a better understanding of the retaining ligaments in the cheek and beyond, which may have a significant impact on tissue mobility, particularly during larger repairs.¹³

On the hands, patients should similarly move through flexion and extension, and should be asked to make a fist. Querying the patients regarding occupational and leisure activities may also be particularly helpful, as a dorsal hand repair on a masseuse may be approached differently to that on a professional golfer. The potential for range-of-motion variation is also seen on the upper back, where baseline patient posture may affect the planned closure vector.

Linear closures near free margins should be carefully planned and assessed, and patients should understand potential risks, such as ectropion or eclabium, before the procedure is started. When assessing the potential for ectropion, the patient may be asked to gaze upward with their mouth wide open while in a semi-reclined position in order to better assess the potential for ectropion development.

As part of the informed consent process, the patient should understand that there will be a scar every time the skin is cut. The goal is not to avoid scarring altogether, which is impossible regardless of surgeon or surgical technique; it is to create the least cosmetically obvious scar while definitively treating the underlying disease process. The assessment of scar quality has been the focus of renewed interest of late, particularly as this may be used as an outcome measure for quality-of-care assessments. The SCAR scale (Scar Cosmesis Assessment and Rating scale) is a recently developed validated scale that may be particularly helpful when determining the quality of postoperative scarring.^{14,15}

The informed consent and consultation process, while unique to each patient's circumstances, should always move through the same steps. Thus all patients are handed a mirror and asked to confirm the surgery site prior to marking, and then again asked to confirm the site verbally once the site has been marked. This approach is invaluable in engaging the patient as partner regarding biopsy-site identification, and may help limit potential liability exposure in cases where wrong site surgery is alleged. In cases where the biopsy-site location is equivocal, surgery should be delayed, and consultation should be undertaken with the referring physician (if applicable), or a small scouting biopsy may be performed.^{16,17}

Prior to beginning the surgical procedure, the patient should be informed of the postoperative healing course. This includes a detailed explanation regarding limitations on physical activity, as well as an explanation regarding postoperative wound care. Furthermore, most patients (and many physicians) are not aware of the need to hyper-evert the wound edges postoperatively, and explaining that this is analogous to a subcutaneous splint that is present only temporarily until buried suture absorption is complete may be very helpful.¹⁸

LINEAR CLOSURE DESIGN AND GEOMETRY

The apical angle: fusiform and rhombus closures

Classic descriptions of linear closure designs have highlighted the role of the apical angle as a determinant of dog-ear formation. The dogma of the 3:1 (or, more recently, 4:1) ellipse with 30-degree apical angles requires significant

revision, particularly as geometrically, even a 3:1 fusiform closure mathematically cannot yield 30-degree apical angles.^{9,10,19}

Angulated (also known as tangent-to-circle and rhombus) closure designs, already advocated by Bennett in the 1980s, have also become more popular, as they permit narrow apical angles (in the neighborhood of 30 degrees) coupled with a relatively modest length:width ratio of approximately 3:1. Indeed, a 3:1 fusiform design results in a 74-degree apical angle, while a similar length-to-width ratio designed as a rhombus yields apical angles of only 37 degrees.

Another modification that blends the benefits of the rhombus design (narrower apical angles coupled with a shorter overall incision length) and the fusiform design (a gradual curving shape that is more amenable to closure without residual central gaping) is the inside rhombus-outside fusiform technique. Here, a rhombus design is first created and incised to the superficial dermis. At that point, lateral pressure on the incision (a technique that is useful in general to avoid overhanging dermis, as noted below) is used to turn the outside edges of the excision site into a fusiform shape while allowing the excised segment of skin to remain as a rhombus, albeit with overhanging dermis on its midsection (Figs. 18-2 and 18-3).

Figure 18-2. The inside rhombus-outside fusiform technique involves incising a rhombus shape initially and then aggressively pressing outward with the blade during subsequent passes.

Figure 18-3. This leads to a defect that is shaped like a rhombus with narrow apical angles but a wound contour that appears more fusiform.

TOPOGRAPHY

The three-dimensional topography of the wound should also be considered when designing a linear closure.¹¹ Indeed, restoring—or maintaining—the natural contours may be at least as important as repairing a wound with a thin scar.^{20,21} For wounds over convex surfaces, designing a straight-line fusiform closure may lead to both short- and long-term undesirable outcomes. In the short term, dog-ear formation may be exaggerated over the extremes of convex surfaces, and such standing cones may not be resolved using standard dog-ear correction techniques (see [Chapter 19](#)). This is the origin of the “chasing the dog ear” phenomenon that may be seen classically when working on the forehead. In the long term, scar contraction occurs three dimensionally; when lateral scar contraction occurs over a convex surface,

this may lead to a clinically apparent depressed scar.¹¹ Several approaches may be used to mitigate this risk, including the S-plasty.^{22–25}

Cosmetic subunits

Keeping a linear closure within a cosmetic subunit, and ideally along a cosmetic subunit boundary, may help lead to an ideal scar.^{1,20} Even very large defects may be hidden very effectively as long as the suture line, however lengthy, remains along cosmetic subunit boundary lines (Figs. 18-4 through 18-6). One of the central advantages of the linear closure design is that it results in a single fine line that is often effectively hidden. Flap repairs by their very nature result in angulated scars, and even with precise suturing techniques, these scars may remain visible, with pin-cushioning a possibility as well.¹ Angulated or geometric scars, once thought to be less obvious to the observer, may actually result in inferior cosmesis, and therefore excisions performed with this goal in mind should probably best be avoided.

Figure 18-4. Moderately-sized defect after Mohs micrographic surgery for basal cell carcinoma.

Figure 18-5. Largely linear repair respecting cosmetic subunit boundaries. Note the downward push on the lip caused by central axis lengthening.

Figure 18-6. Six-month postoperative view showing a nearly undetectable scar and no residual push on the upper lip.

Tension vectors

Understanding and planning for tension vectors parallel to RSTLs and perpendicular to free margins is an important component of linear excisions and repairs. Preplanned ideal tension vectors are not uniformly reliable, even when designed by experienced dermatologic surgeons.^{26,27}

Moreover, the tension vector of the *suture line* is not necessarily the same as the tension vector of the *sutures*; since the tension vector of the sutures dictates the direction of tissue movement, this has important implications for reconstructive design (Fig. 18-7). For example, repairs on the upper cheek or near the lower orbital rim are often closed in a linear or S-plasty fashion. To conform to RSTLs, portions of the excision may lay parallel to free margins such as the lower eyelid. By maintaining the tension vector across the sutures parallel to the free margin, an ectropion-free closure may be accomplished.

Figure 18-7. Orienting the tension vector of the sutures parallel to the free margin can permit closures without free-margin distortion.

The RSTLs over extremities do not consistently conform to the angle of minimal tension under all circumstances, since range of motion has an impact on tension. For example, on the thigh, the true RSTL may be along the long axis with extension but along the transverse axis with flexion. The

anticipated range of motion for the patient should therefore be addressed, and at times utilizing the average of the two angles—the mean RSTL—may be a helpful approach.

Moreover, conforming to the RSTL is not necessary or ideal in all cases. For repairs on the forearms, the RSTL would dictate closure along the long axis of the forearm. Yet given the convex surface of the forearm, this would also increase the risk of long-term dog-ear formation with scar contraction, necessitating a longer scar length. Transverse closures on the forearms may result in cosmetically more appealing closures given the ability to minimize the excision length. Conversely, for dorsal hand closures, the RSTL may run transversely, though closures are often best aligned along the long axis to minimize the long-term risk of lymphedema.

Free margins

Free margins, such as the lips, eyelids, alar rims, and helical rims, are both more susceptible to distortion (given their lack of bony attachments) and more cosmetically obvious when distorted (given their prominence in facial cosmesis) than other areas on the face. Therefore, preserving the position of the free margins is of great importance. Free margins can be both pulled (as in a lower eyelid ectropion caused by downward pull on the lower lid) and pushed (as in an upper lip closure forcing a section of dog-ear downwards). Keep in mind the potential for central axis lengthening as a result of wound closure, as this “pushing” effect due to the differential between the length of the central axis (apex to apex) and the (longer) length of each of the outside wound edges means that postoperatively the length of the linear closure will be longer than anticipated; this may impact repairs around the lips, where tissue may be pushed leading to an immediate postoperative puffiness which often resolves spontaneously.

Evaluation

A bright light and/or Wood’s lamp is very helpful in adequately assessing clinical tumor margins. Sidelighting as well as gently rubbing the lesion with an alcohol wipe and manipulating the skin are all helpful techniques.

Surrounding skin should be evaluated as well; this serves to both ensure that there is no local inflammation that may impede wound healing (seborrheic dermatitis, angular cheilitis, etc.) and to assess whether the postexcision defect will impinge on other preexisting nevi or other skin lesions. For example, a banal nevus that was just lateral to a newly excised dysplastic nevus may appear directly adjacent to the scar line postoperatively. This should be noted and reviewed with the patient so that a focal area of pigmentation adjacent to the scar line is not confused with recurrence.

Scars elsewhere on the patient's body should be evaluated as well, if possible. This serves two purposes: first, it provides a baseline measure for the surgeon regarding the patient's propensity to heal with hypertrophic or telangiectatic scarring. Second, it provides a reference point for patient education, so that the patient may be told what to expect in terms of healing relative to their existing scars. It may also be a significant motivator for encouraging adequate postoperative compliance.

Determining excision size

Dermatologic surgeons perform linear excisions for many indications, including the treatment of nonmelanoma skin cancers, dysplastic nevi, banal or congenital nevi, cysts, and lipomas. For both melanoma and nonmelanoma skin cancer, various studies have examined appropriate surgical margins.^{28–37} See also [Chapters 46 to 48](#) regarding management of specific tumor types.

With time and experience, dermatologic surgeons may trend toward smaller excisions with tighter margins for most low-risk nonmelanoma skin cancers, though maintaining wide and deep margins for melanoma resection remains of critical importance to minimize the risk of potentially catastrophic recurrence.

Benign nevi may be excised en bloc or in segmental or staged fashion. Benign subcutaneous tumors may be excised via modestly sized access incisions and then dissected out subcutaneously to minimize the size of the postoperative scar.

LEARNING LINEAR REPAIRS

Several studies have evaluated techniques to both learn and assess surgical competency and technique.³⁸ Objectively assessing surgical skills is critical, as novice surgeons tend to significantly and consistently overestimate their competence.³⁹ Breaking down surgical excisions and repairs into their component parts, and focusing on particular quality metrics and checkpoints at each step, may be very helpful when learning these techniques.^{40,41}

Of all skills, eversion is least often performed successfully by applicants to dermatologic surgery fellowship programs, suggesting that further focus on meticulous everting suturing techniques, including the set-back suture and buried vertical mattress suture, may be of significant didactic value.^{42–44} While one study questioned the value of eversion per se as a contributor to postoperative cosmesis, it may represent a surrogate endpoint for meticulous wound-edge approximation and tension reduction.⁴⁵

OPERATIVE TECHNIQUE

The excision with linear repair may be broken down into several component parts.

Preparation

After the informed consent process and preoperative consultation are completed, the skin is prepped and infused with local anesthetic (see [Chapter 12](#)). A sterile skin prep is generally performed for dermatologic surgery excisions, though data have suggested that the use of sterile gloves for brief and straightforward procedures may not confer a reduced risk of postoperative wound infection.^{46–48} Common surgical scrubs include chlorhexidine and povidone–iodine; the former confers the advantage of rapid onset of action even while wet,⁴⁹ though chlorhexidine should be kept out of the eyes and ears due to risks of keratitis and ototoxicity, respectively.⁵⁰

Marking

Skin marking is important when preparing for linear closures; many surgeons draw a fusiform (or rhombus) shape to delineate the planned excision.

Another approach that minimizes the amount of tissue marking used is to draw only minimal markings that outline the closure vector, closure extent, and margins around the lesion to be excised (Fig. 18-8).

Figure 18-8. Minimal markings that outline the closure vector, closure extent, and margins around the lesion to be excised can be used. This provides key information to the assistant for local anesthesia infiltration while using a minimal amount of ink that may later need to be removed.

Regardless of the planned defect shape, it may be useful to mark additional anatomic landmarks as well. On the face, cosmetic subunit boundaries may be marked prior to local anesthetic infiltration (Fig. 18-9). On the extremities, particularly when more than one vector appears *a priori* appropriate, both vectors may be drawn out and prioritized (Fig. 18-10). Finally, when working around tattoos or near large superficial vessels, pacemaker leads, or other structures that should be avoided, these may be marked as well in a clear and consistent manner (Fig. 18-11).

Figure 18-9. Cosmetic subunit boundaries may be marked prior to local anesthetic infiltration. **A.** Preoperative photograph. **B.** Postoperative photograph.

Figure 18-10. Multiple tension vectors may be drawn out if needed and sufficient local anesthetic may be infused to use either vector. A circular excision may be performed and the lowest tension vector can then be chosen.

Figure 18-11. Marking structures to be avoided in a clear manner is a helpful preoperative step.

Most dermatologic surgeons use felt-tipped surgical marking pens given their ease of use and low cost; patients should be told that any residual ink may be removed with alcohol. Other options include gentian violet, specialized white tissue markers, and white eyeliner markers.

Local anesthetic infiltration

Local anesthesia revolutionized the field of surgery in the late 19th century.⁵¹ Patients judge the quality of their surgeon based largely on the painlessness of the procedure and the absence of long-term scarring. Particularly given its impact on patient anxiety, adequate and comprehensive local anesthetic infiltration is a prerequisite for successful dermatologic surgery. For smaller cases, direct infiltration is effective. For larger surgical sites, a ring block, nerve block (if possible), or tumescent anesthesia may be considered. For a detailed discussion of local anesthetic infiltration, see [Chapter 12](#).

Incision

After sterile skin preparation and draping, the lesion is excised. The ideal scalpel entry angle for a fusiform excision has been classically described as 90 degrees to the skin;⁴¹ others have suggested a 10-degree outward (reverse) bevel, while more recently, it was suggested that a more dramatic reverse bevel may be desirable.^{52,53} In practice, when working on facial skin or on the forearms, true perpendicular incision angles work well; on the back, particularly in younger patients with a robust dermis, a reverse bevel may be advantageous and minimize the need for removal of any residual overhanging dermis ([Figs. 18-12 through 18-20](#)). This is particularly an issue as after the initial release of epidermis and superficial dermis there is a tendency for the outside (nonincised) edges of the excision to spring laterally ([Fig. 18-21](#)).⁴¹ Stabilizing the surrounding skin during scalpel entry and during incision creation may help maintain a consistent angle.

Figure 18-12. An incision is made along the marked axis with the blade held perpendicular to the skin or with a slight outward bevel.

Figure 18-13. The incision is made to a uniform depth including the apices.

Figure 18-14. The specimen is incised at a uniform depth on its undersurface.

Figure 18-15. Sharp undermining is performed with surgical scissors or a scalpel.

Figure 18-16. The apices are undermined extensively.

Figure 18-17. A fascial plication suture is placed to reduce tension and decrease the apical angle further.

Figure 18-18. Tightening this suture leads to narrower apical angles.

Figure 18-19. After a single fascial plication suture is placed, the bulk of the wound is closed and tension is reduced.

Figure 18-20. Set-back or buried vertical mattress sutures are then placed, allowing the wound edges to drape together under minimal tension.

Figure 18-21. After incising and tissue release, there is a tendency for the lateral edges of the wound to spring back from the central defect.

Most standard descriptions call for the tip of the scalpel to be used initially, followed by the belly of the blade which is ostensibly sharper than the tip. While common surgical folklore, this is more critical when using the larger #10 blade than when using the #15 blade that is typically used in dermatologic surgery. Similarly, references to holding the surgical blade like a violin bow are largely a result of translating general surgery techniques to

dermatologic surgery. The violin bow technique is classically described when using a #10 blade, which is significantly larger than the #15 blade. Similarly, some textbooks historically advocated that a single pass of the scalpel should incise through epidermis, dermis, and through to the subcutaneous fat; in practice, this is both unnecessary and difficult to achieve unless excessive force is used. Therefore, the surgical blade may be held like a pencil and careful and consistent traction may be used to permit a smooth incision through the dermis, though multiple passes, particularly when working on the back, are perfectly acceptable.

Tissue release

Uniform excision and tissue release are very helpful in elegantly excising tissue and preparing the nascent wound for reconstruction. The tendency to bevel the excision inward at the apices may result in the rowboat deformity, which increases the risk of dog-ear formation unless the excess tissue is separately removed prior to reconstruction. Therefore, excision to a uniform depth and with a uniform angle is desirable. A well-planned excision saves significant reconstructive time by obviating the need to trim overhanging dermis prior to wound closure.

Some authors have referred to the “lagging fat” phenomenon, where the epidermis and dermis tend to retract away from the center of the wound after tissue release, but deep fat—without lateral fibrous attachments—lags centrally and presents a physical impediment to wound closure.⁴¹ In clinical practice, there is often a significant lagging *dermis* phenomenon, where even with a 90-degree perpendicular incision a significant amount of reticular dermis may protrude centrally, particularly in areas with a more robust dermis such as the back. This may be obviated by either excising tissue with a reverse bevel or, after the fact, by trimming the lagging dermis (Fig. 18-22). Importantly, no degree of suturing technique-based correction can solve this physical problem definitively, and investing a few moments in assuring that the wound edges are uniform prior to closure is time well spent.

Figure 18-22. Trimming any lagging dermis a critical step that must always take place if dermis is present medial to the epidermal edge.

Undermining

Undermining serves several purposes. First, it permits closure of large (based on defect size) or tight (based on lack of elasticity, such as on the scalp and lower leg) defects under tension that would otherwise not close easily. Second, it reduces tension across moderately tense defects by recruiting adjacent skin for the closure. Third, it frees up underlying attachments that would otherwise lead to both lateral and downward pull, potentially leading to wound inversion.

It is important to undermine the apices as well as the lateral portions of the wound.¹¹ In fact, wide apical undermining may in some cases be *more* important than lateral undermining given its potential to partially mitigate dog-ear formation.

Disadvantages of undermining include its potential impact on blood supply, as wide undermining essentially creates a small local random pattern flap.⁵⁴ Undermining also increases intraoperative morbidity, by creating a potential space for hematoma or seroma formation.

The plane of undermining has a profound effect on surgical outcomes, as it may affect the risk of bleeding (and the resulting need for more aggressive and time-consuming hemostatic measures), as well as the risk of nerve damage. Remaining in a uniform plane is important, and may be aided by retracting back the skin with uniform pressure.

Novice dermatologic surgeons often prefer to err on the side of remaining superficial, and have a tendency to attempt all undermining at the level of the superficial fat, fearing an increased risk of bleeding or nerve compromise with deeper undermining. Understanding the vascular supply of various anatomic areas may be helpful, as overly superficial undermining may also increase the risk of damage to perforating vessels supplying the dermal plexus, decreasing vascular supply and increasing the risk of necrosis. Deeper undermining may permit the reapproximation of deeper, well-vascularized structures rather than only the relatively thin dermis and epidermis. This phenomenon may be seen when performing a linear closure on the nose, where deep submuscular undermining affords a robust vascular supply to the advancing wound edge, while superficial subdermal undermining leads to a significant risk of postoperative necrosis.

When undermining, keep in mind that a scalpel and scissors work from opposite directions: the scalpel cuts from the distal point to the more proximal point, while scissors begin cutting proximally and extend the incision distally.

One recent study evaluated the relative merits of wide undermining and imbrication.⁵⁴ In this porcine study, both undermining and imbrication were studied to assess their effect on wound tension and perfusion. Not surprisingly, both techniques led to decreased tension across the surface of the wound, and both led to a marginal drop in wound perfusion, though imbrication was associated with a slightly more dramatic decrease in perfusion. Notably, the experimental wounds were undermined a full 4 cm, significantly beyond the point that most surgical wounds are undermined in dermatologic surgery.

When feasible, undermining should be minimized in patients on thrombolytic agents such as aspirin or in those with very ruddy skin who are prone to numerous small wound-edge bleeding vessels.

Pragmatically, undermining is best performed under direct visualization. Sharp dissection may lead to less tissue trauma as it avoids shearing forces that may be seen with blunt or spread undermining. While many surgeons

prefer blunt-tipped surgical scissors, such as blepharoplasty scissors (for almost all cases) or Metzenbaum, facelift, or Mayo scissors (for larger cases), on a practical level sharp undermining may also be performed with a scalpel, or using electrocautery on either a pure-cut or blend setting. Radiofrequency cutting devices, as well as newer cold plasma devices, may also be used. These confer the advantages of reduced thermal injury though they are also associated with a significantly increased cost that makes them impractical for most linear excisions and repairs.

Hemostasis

Achieving adequate hemostasis prior to wound closure is an absolute requirement. Experience is very helpful in distinguishing between low-level wound-edge oozing that may resolve with suturing and pressure, and true bleeding that should be addressed with aggressive hemostatic measures. There is a delicate balance between mitigating the risk of hematoma formation and overly desiccating wound edges that may impair healing over the long and short terms. Larger vessels should be clamped and ligated, rather than treated with electrosurgical approaches, in order to minimize the risk of bleeding in the acute postoperative period. Bipolar forceps may be useful, though they are not necessary.

Bleeding should always be addressed under direct visualization, and skin hooks—usually used as a pair to tent up the overlying epidermis and dermis—may be very helpful for this purpose.

Suturing

Suturing techniques affect the efficiency of surgical reconstruction, and suturing technique choice may also impact overall linear closure design. A detailed discussion of suturing techniques and their variations may be found in [Chapter 13](#).

Historically, most linear closures relied on a bilayered closure approach, with sutures placed in the dermis for tension relief and transepidermally for wound-edge approximation. This paradigm has shifted over the past few years, with the realization that recruiting deeper tissue planes may have a profound effect on wound strength and cosmesis.^{55,56}

Fascial plication is one of the most useful techniques for linear closures, as it confers several advantages simultaneously.⁵⁵ First, it leads to significant tension reduction over the wound surface by shifting tension to the deep fascia. Second, it decreases the amount of undermining needed to permit effective closure, theoretically improving vascular supply to the undersurface of the advancing wound edges and reducing the risk of potential space formation that may increase the risk of hematoma formation. Finally, fascial plication has a significant effect on wound geometry, as a single fascial plication suture shifts a wound from a 3:1 fusiform shape to a 6:1 ratio and decreases the apical angles significantly.⁵⁵

Fascial plication sutures need not be used for all linear closures. This technique is most appropriate for areas under significant tension, or large excisions where minimizing the postoperative wound length is desirable. On the face, recruiting the SMAS may be very helpful. When designing the closure of a round defect, the fascial plication suture should be placed prior to removing the dog ears. The risks of fascial plication sutures include possible pain, a theoretically increased infection risk (since the fascial envelope has been pierced by suture), and a theoretical risk of vascular compromise through inadvertent pressure-induced ligation of perforating vessels. In practice, these complications are infrequent, though patients may experience transient pain during needle entry and immediately after the fascial plication suture is tied. If pain persists for more than 5 minutes, the suture should be removed.

Buried dermal sutures are the cornerstone of linear repairs. Two central suturing techniques are useful: the buried vertical mattress suture and the set-back dermal suture. The former yields significant wound-edge eversion and epidermal approximation, while the latter is easier to execute. A randomized controlled trial has suggested that the set-back suture leads to cosmetically more appealing scarring than the buried vertical mattress suture.⁴² Its ease of use is a significant advantage as well, particularly as effective wound-edge eversion is one of the most challenging (and clinically critical) components of the linear excision and closure.³⁸

Set-back dermal sutures result in marked wound-edge eversion, though this can be adjusted based on how far each set-back bite is taken from the incised wound edge. For a detailed discussion of step-by-step suture placement, see [Chapter 13](#).

Though many manuscripts and chapters addressing linear closures advocate the placement of a key suture in the center of the wound followed by closure using the rule of halves, in practice this may be less desirable than starting at one edge of the wound—typically the edge most distant from the surgeon—and moving proximally. The latter technique allows tension to be gradually relieved, minimizing the tension across any single suture. This permits tissue creep to gradually take place over the course of the closure.

The set-back or buried vertical mattress sutures may be placed closer together in the center of the wound, where tensile forces are the greatest. After placement of a full row of buried sutures, the wound edges should be well everted, and ideally drape together under no tension. With assiduous attention to detail, this layer of sutures may lead to ideal wound-edge approximation, obviating the need for transepidermal sutures.

If transepidermal sutures are placed, they may be performed in a simple interrupted or running fashion. Ideally, there should be no tension across the wound surface after deep suture placement, and therefore running sutures may be appropriate. Alternatively, some mild depth correction may be needed and in such cases depth-correcting simple interrupted suture can be used. Running horizontal mattress sutures, often with intermittent simple loops, may also be helpful for yielding excellent wound eversion and avoiding suture material crossing over the incised wound edge.^{57,58} Running subcuticular sutures may be used as well, though in the context of well-placed buried sutures, they often confer only minimal advantage while introducing additional foreign body material across the wound.

Most dermatologic surgeons use reverse-cutting needles; these confer several advantages, and may theoretically decrease the risk of suture material tear-through since the cut edges are on the opposite sides of the vector of maximal postoperative tension.

VARIATIONS

S-plasty

The S-plasty variation of the linear repair is useful for closures over convex surfaces. Given the tendency for linear closures to contract during wound healing, straight-line repairs may lead to scar contraction over convexities

that is particularly visible as scar maturation occurs. By lengthening the overall scar length—and particularly extending the scar length over the convexities—the S-plasty may result in better long-term cosmesis for these repairs.

Some authors have advocated the S-plasty as a technique for all closures, arguing that the extended scar leading to decreased lateral contraction may ultimately provide a superior cosmetic result even in the absence of a convexity.⁵⁹ This theoretical benefit should be weighed against the desire for a straight-line linear repair. Some variations of the S-plasty use shortened or differentially angled arms to reduce the overall incision length, or rely on suturing techniques to add curvature to an otherwise linear repair.¹⁰

When orienting the S-plasty, the curved tips of the repair should follow the RSTLs as much as possible. All S-plasty repairs should be conceptually repaired using the rule of halves, which in practice requires that all sutures are placed perpendicular to the excision (Figs. 18-23 through 18-26). If this is not done, a defect incised as an S-plasty may ultimately appear as a longer straight line.

Figure 18-23. An S-plasty may be used when working over a convex surface, such as the forearm.

Figure 18-24. The S-plasty incision is made to a uniform depth.

Figure 18-25. The excision is performed leaving an elongated S-shaped defect.

Figure 18-26. A fascial plication suture may be used to reduce tension and increase the apical angles.

Eccentric parallelogram

The eccentric parallelogram has been advocated as an alternative to both the fusiform and rhombus repair.¹⁰ This approach provides some geometrical advantages, though like the S-plasty it results in a curved final scar. A variation of the eccentric parallelogram may also be performed using a triangle–square–triangle technique that may result in a straight-line closure.

Crescentic excisions and sides of unequal length

Since a goal of all surgical repairs is to hide the postoperative scar as effectively as possible, some scars may be purposely curved for optimal cosmesis, such as those in the nasolabial and melolabial folds. When designing a crescentic excision, the curved side will dictate the final angle of the repair as long as suturing is performed using the rule of halves.

Occasionally, a defect will be created with two sides of unequal length. This may occur in the context of a linear closure, after attempting to repair a dog ear, or from the secondary defect (or shifted standing cone) of a flap repair. Specialized suturing techniques have also been proposed for repairing wounds with unequal side lengths (Fig. 18-27).

Figure 18-27. The running pleated suture is sometimes used when repairing wounds with unequal side lengths, though following the rule of halves is often a more straightforward approach.

Circular defect with dog-ear repair

Not all linear closures must begin as fusiform or rhombus shapes. Indeed, several studies have suggested that the round excision with ensuing dog-ear correction may yield a shorter postoperative scar than primarily designed fusiform closure. An additional advantage of this freestyle technique is that the ideal closure vector can be determined once the central defect has been created, a significant advantage as even experienced dermatologic surgeons do not consistently select the ideal closure vector.^{26,27,60}

This approach is particularly useful when performing a large excision, where the ideal vector of tissue closure is not *a priori* obvious. This approach also provides an easily oriented specimen for the laboratory. The excision is performed to conform to the native margins of the lesion being excised. It is carried to the appropriate depth, and a perpendicular incision is made circumferentially to minimize the risk of residual overhanging dermis. Once the excision is completed and the specimen is appropriately tagged, wide undermining may be performed and the different potential angles for closure are explored. A fascial plication suture along the appropriate axis may be useful prior to contemplating dog-ear removal, as this may limit the amount of additional tissue that needs to be excised. After dog-ear removal, the wound is then closed in a layered linear fashion.

A detailed discussion of dog-ear repair techniques may be found in [Chapter 19](#).

Delayed dog-ear repair

The tendency toward standing cone formation at the apices of a linear excision is a function of (a) tissue bunching and redundancy; (b) wound edema; and (c) a more pronounced central depression. As two of the three causes of immediate dog-ear appearance are only temporary, it may be preferable to err on the side of taking a smaller dog ear at the time of closure. This must be weighed against patient concerns in the immediate postoperative period regarding the appearance of the nascent dog ears, as some patients are less concerned regarding postoperative cosmesis and would prefer to have a shorter scar. Additionally, especially in areas such as

the lower leg that are at high risk of dehiscence, creating the smallest possible wound is a clear advantage.

M-plasty

M-plasty can be conceptualized as a small V-Y closure at one pole of an otherwise linear repair, and is useful for reducing the length of a linear closure. This approach is classically used around the eyelids, where the M-plasty may be hidden along the rhytides, though it can be used in any situation where a standard dog-ear repair would approach free margins or adjacent cosmetic subunits. The net result of M-plasty formation is that the dog-ear length is reduced by approximately 1/2. For a detailed discussion of dog-ear repair techniques, see [Chapter 19](#).

Nonundermined repairs

While undermining is a standard technique to facilitate both lateral tissue movement and permit the placement of deeper buried sutures (such as the set-back suture), it is neither necessary nor appropriate in all situations. As noted above, undermining itself leads to some vascular compromise as has been demonstrated in a porcine model.

Markedly atrophic skin should almost never be undermined. This is not due to concern regarding skin tear or skiving, but rather because with atrophic skin, the underlying fibrous attachments between the underside of the dermis and the deeper subcutaneous tissues provide the greatest purchase for buried sutures. A modified simple buried dermal suture is used in these cases, taking as large a bite as possible on each side, beginning on the undersurface of the deep subcutaneous tissue or even underlying fascia. Avoiding undermining may permit such wounds to be closed easily without resorting to adjuvant approaches such as suturing through tissue adhesive bolsters.^{61,62}

Second, wounds in areas of very poor baseline perfusion, such as the lower legs, may sometimes be repaired without undermining. This serves two purposes: first, it obviates the risk of perfusion reduction secondary to undermining proper, and second, it creates a smaller subdermal defect in the event of dehiscence.

Partial closure

Partial wound closure may be considered in areas where there is extreme wound tension across the central portion of the defect, such as those on the scalp and lower leg. In such cases, the poles of the wound may be approximated in a linear fashion, but a central area of wound gaping may remain. One option for these repairs is via a Burow's graft, taken from one of the poles of the wounds (see [Chapter 28](#) for a detailed discussion of skin grafts), though permitting this small area to heal by secondary intention is appropriate as well. Adequate patient preparation is of course a prerequisite to this approach.

Another technique for partial closure is used when extreme tension across a wound does not permit direct side-to-side wound apposition at all.⁶³ While traditionally other repairs would be entertained, in select patients, partial linear closure allowing the remainder of the wound to heal by secondary intention may be appropriate. This can be conceptualized as a strategy to reduce the size of the defect that will heal by secondary intention. Such repairs may also be performed prior to skin graft placement.

At times, portions of an otherwise linear repair may be purposely left to heal by secondary intention. For example, when recreating the alar groove, the deepest part of the groove may be left to heal secondarily (or grafted) as an alternative to inverting suture placement.

Staged (serial) excision

When excising a large benign lesion, such as a congenital nevus, staged excisions may permit wound closure with a smaller ultimate repair size than would be needed otherwise. This approach combines several fundamental principles, including tissue creep, tissue stretch, and the ability to perform all but the final stage of the repair as purse-string closures to minimize the final scar length. Other approaches, including a torus (doughnut) approach to staged excisions, as well as a compressed design method using an X-shaped repair, have been described as well.⁶⁴

Multidirectional vector excision

The multidirectional vector excision was proposed as a single-stage alternative to the staged excision for the removal of benign lesions. With this technique, multiple small triangular shaped sections of the benign lesion are pulled with skin hooks in order to determine the optimal closure vector.⁶⁵ Future investigation is needed regarding this niche technique.

Special considerations for post-Mohs repairs

Repairing a defect after Mohs surgery may be conceptualized similarly to the circular defect approach. In addition to wide undermining and the determination of optimal dog-ear removal angles, post-Mohs surgery repairs also should often be debeveled prior to closure. Moreover, sometimes the post-Mohs defect should be deepened prior to closure in order to ensure that closure takes place in the optimal tissue plane.

SPECIAL ANATOMICAL CONSIDERATIONS

Eyelids

Linear repairs on the upper eyelids may be performed as long as significant postoperative asymmetry is not anticipated. If this occurs, a modified blepharoplasty on the contralateral lid may be performed to restore symmetry. On the lower eyelid, excisions may be designed parallel to the lower lid as long as the tension vector across the sutures is perpendicular to this axis (Figs. 18-28 through 18-32). If needed, a stress maneuver with open-mouth and upward gaze should be performed prior to closure design. Keep in mind that Frost sutures (Fig. 18-33) do not mitigate the risk of ectropion due to poorly designed repairs; they simply prevent this occurrence secondary to edema in the immediate postoperative period. For a detailed discussion of eyelid repairs, see [Chapter 38](#).

Figure 18-28. A defect near the eyelids can be closed in a linear fashion as long as tension vectors are considered.

Figure 18-29. The first suture is placed with the goal of maintaining tension vectors parallel to the free margin.

Figure 18-30. The second half of the suture is placed.

Figure 18-31. Note that the suture material is oriented horizontally so that there will be no vertical pull on the lower eyelid, reducing the risk of ectropion.

Figure 18-32. The wound is shown after the placement of an additional buried suture. Note the wound eversion without any evidence of ectropion.

Figure 18-33. A Frost suture may be used to minimize ectropion secondary to postoperative edema in an otherwise well-designed repair.

Nose

Linear repairs on the nose are possible even for fairly large defects, particularly those located in the midline.¹ This approach is predicated on a high length-to-width ratio closure in order to avoid the risk of dog-ear formation at the apices, which is particularly noticeable on the nose. The depth of the excision and suture placement should be significant, as superficially placed sutures and superficial undermining on the nose increase the risk of dehiscence. Buried sutures should ideally include nasalis muscle in order to provide optimal cosmesis.

Patients should be warned that all nasal repairs should be conceptualized as multistaged, given the sebaceous nature of nasal skin. Postoperative dermabrasion is often useful, and if patients are told preprocedure that this may be needed, they will be more satisfied with the ultimate outcome. For a detailed discussion of nasal repairs, see [Chapter 39](#).

Lips

Linear repairs on the lips often heal very well, as long as the white line and wet line are appropriately prioritized. Deep defects should be repaired in a layered fashion, including repair of the orbicularis oris. While silk sutures have traditionally been advocated for the outer layer of lip closures, braided absorbable suture, such as polyglactin 910, is also very soft and may permit layered closure with a single suture packet. For a detailed discussion of lip repairs, see [Chapter 40](#).

Ears

Linear repairs on the ear are often possible and provide outstanding cosmesis. When orienting a repair along the helix, a high length-to-width ratio is helpful in maintaining the natural curvature of the ear. Percutaneous sutures may be helpful (see [Chapter 13](#)) when working with atrophic skin. For a detailed discussion of ear repairs, see [Chapter 41](#).

Cheeks

The cheeks are subject to significant tensile stress and often include significant convex components. Therefore, both S-plasty and crescentic

approaches may be useful. Even large defects on the cheeks can often be closed in a linear fashion (Figs. 18-34 through 18-36). Patients should go through their full range of facial movement before deciding on an optimal tissue vector. Occasionally, M-plasty may be useful when approaching free margins. Fascial plication and set-back sutures are useful for maintaining well-everted wound edges under minimal tension. For a detailed discussion of cheek repairs, see [Chapter 42](#).

Figure 18-34. Lentigo maligna on the cheek can be easily closed in a linear fashion.

Figure 18-35. Wound appearance immediately after SMAS plication and buried suture placement. Note the presence of overhanging dermis that will be removed prior to the completion of the repair.

Figure 18-36. At 6-month follow-up, the wound has healed with barely visible scarring.

Forehead

The forehead is usually repaired in a linear fashion, though closure vectors are of particular importance given the potential impact of repairs on eyebrow positioning. Many small forehead defects are repaired along the rhytides in a transverse fashion, and small defects often result in only temporary eyebrow elevation. Large repairs are best performed in a layered vertical fashion, and

with meticulous suturing technique and eversion, the resulting scar may be almost undetectable. On the temples, wound should be repaired in a radial fashion, with special attention paid to the baseline rhytides and vectors of tissue laxity.

Scalp

Repairs on the scalp should take into account the inelastic nature of scalp skin. Linear repairs are often limited by this inelasticity, though with subgaleal undermining (and possibly galeal relaxing incisions), even fairly large defects may be closed in a linear fashion. There is considerable individual variation in scalp elasticity, and this should always be judged by attempting lateral compression on the scalp in multiple directions prior to closure. Though debatable, considerable tissue creep may be seen in some patients, suggesting a role for intraoperative tissue expansion using either temporary sutures or a towel clamp. For a detailed discussion of repairs on the scalp, see [Chapter 44](#).

Hands and feet

Linear repairs on the hand may be subject to significant tension as well as repetitive trauma from daily exposure as well as the insertion and removal of the hand from a pocket or purse. Most linear repairs on the hand are oriented along the long axis of the hand, though depending on the orientation of the defect as well as the patient's activity level, this axis may be individualized. Transversely oriented closures may increase the risk of postoperative lymphedema due to an increased risk of lymphatic transection. Exploring the full range of motion rather than relying on RSTLs alone is helpful. The loose areolar tissue just beneath the dermis provides an excellent plane for undermining. Use particular caution with transepidermal sutures to avoid inadvertently entering or ligating one of the many small superficial vessels of the dorsal hand. For a detailed discussion of hand and foot repairs, see [Chapter 45](#).

COMPLICATIONS

As with any surgical procedure, bleeding, hematoma formation, dehiscence, and infection are the most common postprocedure complications seen with linear repairs.

Surgeons should make every effort to personally see every patient with a postoperative complication. This both serves to assuage the patient's concerns and helps the surgeon with feedback regarding optimal technique. Additionally, the surgeon is best qualified to assess whether some mild edema or erythema truly represents a complication or whether it is simply an expected part of the healing process.

Dog-ear formation is also frequently seen with linear closures, and a delicate balance between maintaining the natural curvature of the skin and not exaggerating the length of the wound must be maintained. Dog-ear correction should generally not be considered for at least the first few postoperative months, as significant wound flattening and maturation is expected within this period.

Most linear closures do not require surgical drains; for the rare patient with persistent pinpoint bleeding or a background bleeding diathesis, placement of a small Penrose, Jackson-Pratt, or wick drain could be considered, though in general it is far better to achieve adequate and meticulous hemostasis prior to wound closure. A rapidly expanding hematoma necessitates evacuation in the context of surgical revision, where the wound should be anesthetized, prepped in a sterile fashion, opened, explored, and all sources of bleeding definitively addressed. Smaller or stable hematomas may be managed conservatively.

Mild wound dehiscence should be managed with sharp debridement. Usually, local anesthetic is not required as only devitalized tissue—and often only the overlying eschar—is debrided. Patients may be seen weekly if desired, and should be advised to keep the wound bed moist with ointment application at least three times per day. It is vital to debride the advancing edges of the wound in order to maximize the chance of rapid healing. Patients should be told that postdebridement bleeding is not only expected, but desirable as well.

Active wound infections, while rare, should be cultured if possible, and empiric antibiotics may be started. True abscesses should be drained. Patients should understand that even wounds with significant postoperative complications may ultimately heal with outstanding cosmesis.

Repairs on sebaceous skin, such as the nose, may result in a scar that appears depressed relative to the surrounding skin. This may be approached with dermabrasion (or laser) postoperatively, though waiting 3 to 6 months may be prudent as the scar may improve significantly without intervention.

Persistent wound eversion, though rare, may be treated with intralesional triamcinolone injection, though this should not be considered until 6 months have passed.

POSTOPERATIVE MANAGEMENT

Even the best surgical repair can be undone by less-than-optimal postoperative care. Clear written instructions on wound care are of vital importance, and should be reviewed verbally with the patient as well. For most linear repairs, only minimal postoperative management is required. For wounds closed without transepidermal sutures, a simple adhesive film dressing may be applied immediately postoperatively. This gas-permeable film will permit the wound to breathe while providing a moist environment for wound healing. Patients should be warned that a small amount of blood or serous fluid drainage is expected, and that this will typically become trapped beneath the film dressing. The film dressing may be left in place for the next 1 to 2 weeks, depending on patient and surgeon preference. The advantage of this approach is that it requires no effort on the patient's part, particularly useful for difficult-to-reach wounds or for patients living alone. Leaving the dressing in place for more than 2 weeks may increase the risk of maceration.

For wounds closed with transepidermal sutures, film dressings remain an option, though often a nonstick dressing is simply cut to size and placed over the wound after the application of a thin film of ointment.

A moderate pressure dressing is applied postoperatively and left in place for approximately 24 hours. When placing a pressure dressing over adherent film, the gauze should extend beyond the edge of the film so that the adhesive tape holding the pressure dressing in place does not touch the film, as otherwise the film may be inadvertently removed at the time of the first dressing change.

Pressure should be sufficient to mitigate the risk of oozing, but should not restrict blood flow to the wound. Additionally, downward and inward pressure should be exerted just lateral to the wound edges, resulting in a net

effect of the wound edges being pressed together. Direct pressure over the surface of the sutured wound should be avoided, as this does not address potential space created laterally to the suture line and also serves as a distracting force against the sutures. This same principle should be emphasized to surgical assistants when they are asked to hold pressure on a partially sutured wound.

When needed, suture removal may be performed between postoperative days 3 and 10, depending on the anatomic site of the surgery and surgeon preference. For patients who are unable to return for suture removal, options include avoiding transepidermal sutures or placing the transepidermal sutures using fast-absorbing gut or fast-absorbing synthetic sutures.

For wounds covered with an adhesive film, no care is needed. For those covered with a nonstick pad, the wound may be gently cleaned once or twice daily and a thin film of petrolatum should be placed over the suture line using a cotton-tipped applicator. For wounds in dependent areas, patients should be advised to keep their legs elevated as much as possible for several weeks postoperatively.

Patients often ask about using over-the-counter scar healing aids. Most have little or no evidence of efficacy, and in general they should not be recommended. For patients with a history of true keloid formation, consideration may be given to intraoperative or immediate postoperative triamcinolone injection along the suture line, with repeat monthly treatments for maintenance, though risks, including delayed wound healing, atrophy, and telangiectasias, should be discussed with the patient. As noted above, patients should be told to expect dramatic wound eversion postoperatively, and be reassured that this is only temporary.¹⁸

CONCLUSIONS

The linear closure is the most useful and broadly applicable closure technique in dermatologic surgery. One of the great advantages of linear closures is their predictability; since the outstanding blood flow is maintained to the wound edge, these closures often result in fine-line nearly imperceptible scars when carefully designed and executed. Attention to detail and customizing approaches for each individual patient and anatomic

location serves to create closures that will ultimately be difficult to detect from a conversational distance.

CHAPTER 19 Dog-Ear Correction

Philip Milam
David R. Carr

SUMMARY

- Dog ears, apical triangles, or standing cones are seen frequently in dermatologic surgery.
- Management of dog ears ranges from high length:width ratio reconstructive design to direct correction and beyond.
- A variety of approaches are available that are a function of anatomic location, patient preference, and desired level of surgical complexity.

Beginner Tips

- Dog ears may be avoided by appropriate closure design and execution for standard elliptical closures.
- The two most common methods for dog-ear correction are the bilateral-incision and midline-incision extension techniques.
- Post-Mohs defects are often circular and provide good opportunities to practice redundancy removal. Placing a central deep suture forms two dog ears that can be revised using any of the above techniques.

Expert Tips

- More nuanced techniques (M-plasty, S-plasty, Burow's advancement flap) may improve the outcomes in particular cases.
- These techniques are particularly useful on the face and when working around cosmetic subunit boundaries.
- On convex surfaces, specialized techniques, such as the dog-ear tacking suture, can be used.

Don't Forget!

- In certain circumstances, deferring treatment of the dog ear is acceptable.
- S-plasty correction is predicated on suture placement using the rule of halves; otherwise, there is a tendency to keep extending the repair length.

Pitfalls and Cautions

- Beware of chasing the dog ear on convex surfaces; instead, use an S-plasty or dog-ear tacking suture.
- Never treat a false dog ear; err on the side of undertreating, but be sure to outline the plan to the patient.

Patient Education Points

- All dog ears appear more dramatic in the immediate postoperative period than they will after healing; this is a function of local edema, anesthetic infiltration, and increased tension toward the center of the wound.
- Many small dog ears will resolve spontaneously with time; allow at least 2 months to assess the degree of residual dog-ear presence.

- Advising patients that all procedures are staged, so that the dog-ear correction is actively planned for a future date, minimizes stress and frustration.

Billing Pearls

- Engaging in surgical dog-ear correction is one of the ways in which a repair may move from intermediate to complex.
- If dog-ear correction is performed at a later date, be aware that this may be covered under the global period for a repair, particularly if a flap (with associated 90-day global period) was performed.

CHAPTER 19 Dog-Ear Correction

INTRODUCTION

The dog ear, also known as a standing cone, tricone, or apical triangle, is a redundancy of skin that can occur in a cutaneous closure. It can often be avoided with correct planning and a knowledge of basic principles of skin closure techniques, though some closures are designed to purposely leave a dog ear that will need correction.

PRINCIPLES OF DOG-EAR FORMATION

Wound geometry

The risk of dog-ear formation may be minimized and sometimes completely avoided with some forethought and an understanding of simple geometry. While there are many possible geometric shapes to consider for cutaneous surgery, the fusiform excision has long been established as ideal for linear closure of a wound on a flat surface. The best fusiform excision has symmetric edges of equal length, a length:width ratio of 3 to 4:1 and tapers at the ends to form 30-degree angles.¹⁻⁴ It should be noted that this shape is commonly referred to as an *ellipse*, and while this is not geometrically correct, in clinical practice, the terms *elliptical* and *fusiform* are often used interchangeably.

The geometric property that contributes most significantly to the formation (or prevention) of dog ears is the length of the wound edges relative to wound width.² If one visualizes the long axis of the excision as the line which connects the apices, it becomes clear that the sides of the wound are invariably longer than this axis. As closure approaches the apices of the

wound, the movement of the edges becomes more rotational, pivoting at the point of the apex and resulting in compression of the peri-apical skin (Fig. 19-1). When this rotational movement and compression overcome the skin's elastic qualities, a dog ear forms.^{1,3,5} Increasing the apical angle increases the rotational movement, subsequently increasing the risk of redundant tissue gathering at the apex.³ To minimize this risk, the excision should have a length:width ratio of 3 to 4:1, with apical angles no more than 30 degrees.¹⁻⁴

Figure 19-1. In this elliptical excision, the movement at the midpoint of the closure is pure advancement, though the apices rotate slightly as illustrated by the curvature of the lines. This rotational force contributes to tissue puckering and dog-ear formation.

In addition to the length:width ratio, the edges of the fusiform excision should be symmetric to prevent large or unevenly positioned dog ears; if the arcs are unequal, excess tissue will be gathered on the longer side and not be uniformly positioned at the apex. Correction of an uneven dog ear such as this will not result in a linear closure, but will create a curved or angled scar (crescentic repair). This may be advantageous to the skillful surgeon when trying to place a scar within natural skin lines or along favorable lines of tension.

Note also that a 3:1, and even a 4:1, fusiform excision yields apical angles significantly greater than 30 degrees. Therefore, as noted in the previous chapter, some surgeons prefer to utilize a rhombus (tangent to circle) design or other angulated closure.

Tissue dynamics

The elastic properties of the skin are important to consider when planning a closure. Skin is naturally pliant, and can tolerate a certain degree of tension or compression while maintaining a smooth, flat surface. However, the skin has defined limits of malleability, which vary with age, location, and actinic damage.¹ As stated previously, when the imposed forces which are required for closure surpass the skin's intrinsic elastic properties, dog ears can develop.¹

Because each layer of skin is anchored to the structures beneath it, undermining is an essential method for augmenting the skin's functional pliability. As an ellipse is closed, the edges pull on the underlying tissue, compressing the tissue at the base of the wound and causing vertical displacement of the wound edges.^{1,2} Undermining can release the wound edges from the anchored tissues beneath, mitigating the compression by allowing lateral dissipation of pressure as the skin is stretched.^{2,5}

Surface contour

In addition to wound geometry and tissue elasticity, the contour of the surgical site may also affect the closure and formation of dog ears. Because the geometric principles of lines and angles differ between planar and curved surfaces,⁶ the prudent surgeon must account for the curvature of the skin when preparing an excision. Due to these geometric differences, fusiform angles on a convexity should be less than 30 degrees to produce a closure result comparable to that of a similar wound on a flat surface. Conversely, on a concave surface, the wound can often be closed with angles larger than 30 degrees.⁶ In short, closure on a convex surface is more likely to produce dog ears, whereas concave surfaces are more forgiving.^{1,2}

THE FALSE DOG EAR

A distinction has been proposed to differentiate permanent standing cones (*true* dog ears) from those types of skin redundancies which are transient and resolve spontaneously. These temporary redundancies have been termed *pseudo* or *false* dog ears, as they flatten out over time without any intervention. Essentially, a false dog ear is composed of a relatively small portion of skin without an abundance of subcutaneous tissue, and its composition is such that it is able to resolve naturally. The reason these false dog ears will resolve is trifold: (1) there is not excessive underlying tissue; (2) the surrounding skin is sufficiently able to contract and stretch to accommodate redistribution of the excess skin over time; and (3) the dog-ear and wound margins have been adequately undermined.⁵ Properly undermining, especially at the apices, cannot be understated, as this maneuver allows any protruding skin to be pushed deep in the horizontal plane.⁷ Also, as skin is generally more dynamic in younger patients, the chance of full dog-ear regression increases with younger age.⁸ Understanding which dog ears will resolve spontaneously, and which require correction, is often a function of experience.

High-tension repairs, such as those on the lower leg, may also lead to changes that mimic true dog ears. When an ellipse is closed in an area under significant tension, such as the lower leg or scalp, the tension on the skin may cause central wound depression. This depression sometimes causes the tips of the ellipse to appear raised, simulating dog ears; however, this is illusionary due to the central depression. The tips are not truly redundant, and generally resolve without intervention.

TECHNIQUES FOR DOG-EAR REMOVAL

Techniques that excise the excess puckered tissue by lengthening the scar along the wound's long axis are the simplest and most frequently utilized methods of dog-ear revision (Fig. 19-2). Extending the wound increases the length-to-width ratio, thereby decreasing the apical angle, resulting in a more gradually tapered edge which can then be approximated with less rotational compression. With less compression at the apices, the less the tissue will pucker and tent. These methods are best employed when the wound is

already aligned along a favorable line of closure¹; however, sometimes simply extending the scar line will not result in a favorable outcome. In such instances, alternative approaches using more nuanced excision or suturing techniques will allow the surgeon to deliver a superior closure.

Figure 19-2. Techniques for dog ear repair.

The focus of this discussion will be on interventions for dog-ear removal. It is important to remember that leaving the redundant tissue in place with consideration for future revision is acceptable. Often the dog ear will dramatically improve and the revision procedure may involve a much smaller redundancy than was originally planned (Fig. 19-3).

A

B

C

D

Figure 19-3. Delayed dog-ear repair. Dog ears may improve spontaneously over time; even those that do not resolve completely are frequently less conspicuous than anticipated, ultimately necessitating an additional length at revision that is significantly smaller than would have been performed *a priori*. The patient presented with a significant defect of the left upper cheek/lower eyelid (A) that was closed without removing the large superior dog ear (B). At 2-month follow-up, (C) there is a very small area of redundant tissue noted just superior to the left mid nasojugal fold, on a background of slight edema. This small redundancy was removed, and the final result 4 months after the original surgery (D) demonstrates acceptable symmetry with the contralateral side.

Bilateral-incision extension technique

This approach is very straightforward, and can be used in the majority of cases. This is the primary method of dog-ear removal for the authors of this article. With practice, this technique is an efficient and elegant way to repair dog-ear redundancies:

1. Using forceps or a skin hook, grasp the apex of the dog ear and pull lightly in an outward direction until just taut. This maneuver will produce a triangular shape to the cone of tissue, with its base aligned with the original wound incision.
2. With the skin tented, it is important to note the extent of the redundancy, as this will indicate how much wound extension is required. This is denoted by the tip of the cotton-tipped applicator in the figure (Fig. 19-4A).

Figure 19-4. The bilateral incision extension technique. First, (A) the dog ear is gently elevated with surgical forceps, and its extent is noted (here by the presence of the cotton-tipped applicator). Then, (B) the dog ear is gently pulled laterally, and an incision is made in line with the already existing excision line. This nascent flap of skin is then undermined (C). The dog ear is then pulled in the opposite direction (D), and another incision is made. This technique results in dog-ear removal and the extension of the original excision line (E).

3. While lightly gripping the apex of the cone, drape the redundancy to one side. Then make an incision connecting the point of extension (Step 2) with the surgical wound. Particular attention should be paid to creating

an incision that aligns with the existing incision with little to no angle change (Fig. 19-4B).

4. Elevate the redundancy and undermine the flap of skin. This can be accomplished with a scalpel or scissors (Fig. 19-4C).
5. Once undermined, drape the redundant skin across the long axis of the original wound. Incise the remaining side of the redundancy along the long axis to release the tissue. Again, particular attention should be paid to creating an incision that aligns with the existing wound with little to no angle change (Fig. 19-4D).
6. Finally, closure of the wound should continue with a standard linear closure technique (Fig. 19-4E).

Midline-incision extension technique

This technique has the same result as the bilateral-incision method, utilizing a slightly different approach:

1. Using forceps or a skin hook, grasp the apex of the dog ear and pull lightly outward until just taut. This maneuver will produce a triangular shape to the cone of tissue, with its base aligned with the original wound incision.
2. With the skin tented, it is important to note the extent of the redundancy, as this will indicate how much wound extension is required, as is denoted by the tip of the cotton-tipped applicator (Fig. 19-5A).

A

B

C

D

E

F

G

Figure 19-5. The midline-incision extension technique. First, (A) the dog ear is gently elevated with surgical forceps, and its extent is noted (here by the presence of the cotton-tipped applicator). Then, (B) the dog ear is gently pulled upwards away from the skin, and an incision is made in the midline extending the already existing excision line. This area is then undermined bilaterally (C). The dog ear is then pulled gently laterally (D), and the half-triangle is removed in line with the original excision line. Finally, the dog ear is pulled in the opposite direction (E), and the process is repeated (F). This technique results in dog-ear removal and the extension of the original excision line (G).

3. While lightly gripping the apex, incise the redundant tissue directly along the long axis of the wound with a scalpel or scissors, effectively bisecting the cone into two equal triangular flaps. If working with very thin skin, the surgeon may find using scissors an easier approach (Fig. 19-5B).
4. Undermine beneath the dog ear to release the flaps of skin (Fig. 19-5C).
5. With forceps or a hook, grasp one of the flaps and drape it across the incision line (the long axis) (Fig. 19-5D).
6. Remove this flap by excising it at its base along the incision line. Be careful not to impose excessive traction when pulling the flap across the wound, as this will result in excision of excess tissue (Fig. 19-5D).
7. After the first triangular flap is removed, repeat the process with the opposite flap (Fig. 19-5E).
8. Finally, closure of the wound should continue with a standard linear closure technique (Fig. 19-5F).

ALTERNATE INTERVENTIONS

Though most dog ears can be remedied using the aforementioned interventions, in some instances, lengthening of a scar is not possible or will lead to an inferior cosmetic result. These cases may warrant more advanced approaches to achieve superior results.

M-plasty modification

This technique may be employed when lengthening of the scar would yield a suboptimal result, commonly encountered when performing surgery around certain anatomic sites, such as the eye or lip, or when the resultant lengthened scar would cross a cosmetic junction. M-plasty is used to shorten the final scar length, and additionally removes less normal skin:⁹

1. Using forceps or a skin hook, grasp the apex of the cutaneous cone and pull lightly in an outward direction. This maneuver will produce a triangular shape to the cone, with its base aligned with the original wound incision.

2. With the skin tented, note the extent of the redundancy. It may be useful to outline the base of the cone. Mark a point on each side of the cone's base that is approximately two-thirds of the length of the redundancy (Fig. 19-6A).

Figure 19-6. The M-plasty technique. The extent of the raised dog ear is delineated (A), and a point $2/3$ along the length of each cone's base is marked. Incise along the base of the redundancy, connecting one of the points to the existing wound (B). Repeat this step with the second point on the other side. This will result in a flap of skin that resembles a rectangle, which is only attached along one of its long edges (C). Next, excise a portion of the flap by cutting from the midpoint to the point previously marked (D) and repeat on the other side (E). A tip stitch (F) is often utilized to secure the tip of the M-plasty in place.

3. Incise along the base of the redundancy, connecting one of the points to the existing wound. Repeat this step with the second point on the other side (Fig. 19-6B). This will result in a flap of skin that resembles a rectangle, which is only attached along one of its long edges (Fig. 19-6C). Note that the apex of the original wound now terminates at the midpoint of the flap's free edge.
4. Undermine flap of skin, so it can be laid flat on the skin surface.
5. With scissors or a scalpel, excise a portion of the flap by cutting from the midpoint to the point previously marked in Step 2. Then repeat on the other side (Figs. 19-6D and 19-6E).
6. For good approximation of the tip of the M-plasty, a tip stitch (half buried horizontal mattress suture) is often utilized. Suturing of the remainder of the M-plasty is performed in a conventional fashion (Fig. 19-6F).

S-plasty modification

This technique permits redirection of the closure line of redundant tissue. This is particularly helpful on convex surfaces, such as the extremities, the chin, and the ear which often require length:width ratios much greater than the standard 3:1 to reduce the apical angle for optimal closure. Redirection of the excision has two primary benefits: (1) it guides the suture line from the convex surface onto a flatter surface, thereby mitigating the risk of “chasing” the dog ear on the convexity and decreasing the required suture line length; and (2) as scars tend to depress on convex surfaces, S-plasty redirects the depressive forces onto a flat plane, thereby decreasing the formation of such central indentation.

To perform this procedure (Fig. 19-7), the surgeon will follow many of the same steps as the bilateral-incision technique. However, rather than bisecting the cone to a point aligned with the wound's axis, a different point is selected either to the right or left of it. The further right or left the surgeon goes, the more dramatic the S-plasty. Curvilinear lines are created and the edges are undermined as needed. As one edge will be longer than the other, the rule-of-halves should be utilized when suturing to decrease the risk of forming another dog ear: the first suture approximates the midpoint of the long arc to the midpoint of the short arc, essentially halving the wound (Fig.

19-7D); the second suture then approximates the midpoints of the subsequent arcs, and so on, and so forth, the strategy continues, successively halving the wound each time until the closure is complete. The rule-of-halves allows the excess tissue of the longer wound edge to be evenly distributed along the entirety of the wound's closure, minimizing or eliminating the need for redundancy removal.

Figure 19-7. The S-plasty modification. In order to exaggerate the curve at the end of the closure, a target point (asterisk) is chosen outside of the standard dog-ear removal cone, lateral to the base of the standing cone (A). A curvilinear incision is made from the end of the existing excision line to the target point (B), and the dog ear is then draped laterally and removed (C). The first deep suture is placed in the center of the nascent dog-ear repair, using the rule of halves (D). Light tension pulling the new wound apex away from the center of the wound is helped to better delineate the precise location of the center of the repair. The final result (E) is a curvilinear repair terminating at the target point.

Burow's advancement and flap modifications

Redundant tissue needs not be excised only by directly lengthening the already-formed suture line. For example, a Burow's advancement flap may be performed by displacing the apical triangle by as much as 90 degrees. Indeed, advancement, rotation, and transposition of neighboring skin can be used to more appropriately orient a dog-ear removal, permitting the placement of additional wound length in natural creases or along cosmetic subunit boundaries. These techniques are particularly useful when the defect is present in close proximity to the borders of anatomic subunits or close to free margins. Additionally, the redundancy itself can be used for the closure, such as in a V-Y advancement flap ([Chapter 21](#)) and Burow's graft repair ([Chapter 28](#)).

Suturing techniques to decrease dog-ear prominence

Multiple techniques have been reported utilizing suturing techniques to help repair dog ears.^{10–12} They do not replace the aforementioned techniques, but rather can function as helpful adjuncts. They are particularly helpful in the correction of a small redundancy, or when a full-thickness dog-ear excision may compromise the subdermal vascular plexus. This is particularly useful when removing dog ears at the base of flap repairs in areas of poor perfusion, or in patients with comorbidities.

Several reports discuss tacking sutures to reduce the appearance of the dog ear.^{10,11} The dog-ear tacking suture is performed by placing a dermal suture at the undersurface of the apex of the redundancy followed by a suspension suture that grasps periosteum ([Fig. 19-8](#)).¹¹ Another technique utilizing a suspension suture describes a three-bite technique:¹⁰ the first throw is at the base of the dog ear, a few millimeters distal to the last subcutaneous stitch, and grabs fascia or periosteum (the suspension suture); the needle is then passed in a dermal plane (similar to a running subcuticular suture throw) along one side of the dog ear; finally, a third throw is performed along the other side. When the suture is tied, it approximates the skin of the redundancy and tacks it to the underlying fascia or periosteum.

Obviously, both of these techniques are best utilized in areas where underlying periosteum is easily available, such as the forehead.

Figure 19-8. The dog-ear tacking suture.

Another novel method describes de-epithelializing the dog ear, inverting it and suturing over the redundancy.¹² This technique is more technically challenging, as it requires the surgeon to have the precision to de-epithelialize tissue which, in some cases, may be quite thin and difficult to manipulate. As with the suturing techniques described above, this does not require the removal of the subdermal vascular plexus.

CONCLUSIONS

Dog-ear correction is a daily task for the dermatologic surgeon. While some surgeons aim to design linear excisions that *a priori* mitigate the risk of dog-ear formation, others prefer to excise tumors and then correct standing cones on an as-needed basis. In select cases, apical triangles may be left in place to assess their postoperative prominence after the initial healing phase. In defects from Mohs micrographic surgery, most wounds require some degree of dog-ear correction, as the defect is rarely fusiform. Repairing dog ears in a linear fashion is the most common approach, whether using the midline or double-incision approach, though other modifications, including specialized suture techniques and Burow's advancement flaps, are possible as well.

CHAPTER 20 Principles of Flap Dynamics

Cassandra J. Simonetta
Jennifer A. Fehlman
Ian A. Maher

SUMMARY

- Understanding flap dynamics is a prerequisite for the performance of any flap procedures.
- Pivotal, deep, and horizontal restraints all have an important impact on flap design and execution.

- Accounting for fundamental tissue principles and flap dynamics prior to flap execution permits more successful and cosmetically appealing reconstructive outcomes.

Beginner Tips

- Understanding flap dynamics is predicated on an appreciation of the forces that oppose tissue movement.
- Undermining mitigates most deep restraint, while horizontal restraint is addressed by using a sufficiently lengthy incision that recruits lax skin.

Expert Tips

- Horizontal, deep, and pivotal restraints must all be addressed for optimal flap outcomes.
- Obstructive restraint can be addressed prior to flap movement.
- On the face, the robust blood supply means that even random pattern flaps may behave more like axial flaps in terms of viability.

Don't Forget!

- Undermining beyond 1 to 2 cm from the incision line may be counterproductive and lead to an increased risk of tissue ischemia.
- Flap length:width ratios should ideally not be significantly greater than 3:1, at least when working in poorly perfused areas such as the legs. On the face, where most dermatologic surgery flaps are performed, there is often a forgiving and robust blood supply.

Pitfalls and Cautions

- Failing to account for pivotal restraint is one of the most common flap design challenges. Appropriately oversizing rotation flaps and widely undermining the pivot point may go a long way to mitigating this problem.
- Once relocated to the primary defect, flaps should be under minimal tension.

Patient Education Points

- Patients should be warned prior to flap closure that they will have an incision stretching well beyond the initially visible defect.
- Explaining that the additional scar length will likely heal with a minimally visible line may go a long way toward patient reassurance.

Billing Pearls

- Flap repair codes (140XX series) include the excision component, so it is not appropriate to bill both an excision and a flap repair code simultaneously.
- Mohs codes may be submitted along with flap repair codes, though they may be subject to the multiple procedure reduction rule.
- When coding a flap, medical necessity is the ultimate arbiter of appropriateness.

CHAPTER 20 Principles of Flap Dynamics

INTRODUCTION

Flap dynamics are the principles that underpin the movement and behavior of all flaps. By definition, a cutaneous flap is a reconstructive technique that is composed of skin and subcutaneous tissue as well as accompanying vascular supply, which is moved from a donor site to a recipient site. The recipient site is termed the primary defect and, in the context of dermatologic surgery, usually results from the excision of a cutaneous neoplasm. Movement of the flap into the primary defect may create a secondary defect that must also be repaired.

VASCULAR ANATOMY

The skin of the head and neck has a robust vascular system that is derived from the subdermal and epidermal vascular plexuses. In the skin, the deep musculocutaneous arteries give rise to the subdermal vascular plexus, which is found at the junction of the dermis and subcutaneous tissue. Arterioles from the deep subdermal plexus supply the epidermal appendages and give rise to the intradermal vascular plexus. The intradermal vascular plexus is found in the reticular dermis and branches to form the superficial vascular plexus that ultimately becomes the capillary loop system in the papillary dermis. It is this capillary loop system that supports the metabolic needs of the epidermis. Due to low perfusion pressures and blood flow within the intradermal plexus, it is essential that the undermining of a random flap be performed in the plane of subcutaneous tissue. Inclusion of vessels of the

subdermal plexus helps to ensure adequate blood flow and viability (Fig. 20-1).^{1,2}

Figure 20-1. Cutaneous vascular anatomy. The subdermal plexus found in the mid to superficial subcutaneous tissue provides the vascular supply to random pattern flaps. The intradermal vascular plexus lacks the perfusion pressure and bloodflow to support cutaneous flaps alone. Deeper musculocutaneous arteries provide the vascular supply for axial pattern flaps.

STRESS–STRAIN CURVE

The biomechanical properties of skin must be considered in order to ensure flap viability and success. Like all materials, skin has unique and characteristic biomechanical properties: chief among these are stress and strain. In cutaneous surgery, stress is defined as the force applied per cross-sectional area, while strain is the change in the length divided by the original length when a given force is applied to the skin (Table 20-1).

Table 20-1. Stress and Strain

Stress	Strain
Force per unit area	Change in length divided by the original length

The nonlinear relationship between stress and strain can be visualized using a stress–strain curve. This nonlinear/nonelastic property of skin is due to its structural components, mainly collagen and elastin. In the elastic phase (Zone I) of the curve, the randomly oriented elastic and collagen fibers within the skin begin to stretch and orient themselves in the direction of the applied force. This initial deformation results in the lengthening of the tissue with minimal force, and is nearly linear or elastic. In the plastic phase (Zone II) of the curve, as force is continually applied, the lengthening continues as additional collagen fibers become aligned parallel to the direction of the applied force. In the breaking phase (Zone III) on the curve, the collagen fibers are maximally stretched and the lengthening becomes limited.^{3–7} In this final phase, large amounts of force will result in only minimal lengthening of the tissue due to the inextensible nature of fully stretched collagen fibers.⁸ Understanding this stress–strain curve is essential to flap design as high wound-closure tension, as seen in Zone III of the curve, increases the risk for tissue necrosis and flap failure (Fig. 20-2).

Figure 20-2. Stress–strain curve demonstrating the nonlinear properties of skin when stretched. Initial lengthening occurs with minimal force during the elastic phase (Zone I), progressive lengthening occurs during the plastic phase (Zone II), and lengthening ceases despite additional force during the breaking phase (Zone III).

VASCULAR SUPPLY

Adequate vascular supply of a flap is of paramount importance for flap survival. By definition, all flaps provide the vascular supply needed to provide the gas exchange and nutritional support required for their survival. The base or pedicle of the flap is the area that remains attached to the skin adjacent to the surgical defect and contains the source of this vascular supply. The tip of the flap is the portion of the flap furthest from the base, and is the portion of the flap that is most at risk for necrosis and failure secondary to insufficient blood supply.

Various ways to categorize cutaneous flaps exist; one such approach is to categorize flaps according to vascular supply. Using this classification system, the two main categories of cutaneous flaps are random and axial pattern flaps ([Table 20-2](#)). Random flaps include those that are supplied by unnamed arteries. In cutaneous surgery, there are a nearly infinite number of random flaps that can be designed on the face due to the abundant vascular

supply and plentiful anastomoses. Blood supply of random flaps is derived from perforators of musculocutaneous arteries at the base of the flap, and delivered to the tip by the interconnecting vessels in the dermal and subdermal plexuses. Axial flaps, in contrast, are those that incorporate a named artery within their pedicle; this named septocutaneous or musculocutaneous artery runs within the long axis of the flap. When a flap extends beyond the reach of the named artery, the distal portion is functionally a random pattern extension of the axial pattern flap. In dermatologic surgery, the most commonly encountered axial flap is the paramedian forehead flap, deriving its blood supply from the supratrochlear artery.

Table 20-2. Flap Categorization Based on Vascular Supply

	Random	Axial
Blood supply	Unnamed blood vessel	Named artery
Number of options	Infinite	Finite
How frequently utilized	Frequently	Infrequently

In planning a cutaneous flap, various forces that affect end perfusion must be considered. Vascular perfusion pressure is the force of blood flow through a vessel; this force must be greater than the capillary resistance in order to maintain vessel patency. As expected, perfusion pressure decreases as the distance from the feeding vessel increases. If the distance becomes too great, perfusion pressure will fall below the critical closing pressure of the vessel, and necrosis will occur due to lack of blood supply.⁹ This inverse relationship between the distance from the feeding vessel and perfusion pressure historically dictated that flap length:width ratios should be in the order of 3:1 to ensure adequate vascular supply. This theory was challenged by work performed by Stell in 1979 that showed that while viable flap length is dictated by the width of the base, there is an upper limit of length survival that cannot be increased by widening the base of the flap (Fig. 20-3).⁹⁻¹⁴

Figure 20-3. Flap perfusion and critical closing pressure. Perfusion pressure decreases as the distance from the artery and arterioles supplying the flap increases. Once capillary perfusion pressure falls below capillary resistance, blood flow ceases and distal flap necrosis occurs. Note the dependence on location, since areas with higher perfusion pressure, such as the face, are more forgiving.

In addition to perfusion and closing pressures, tension exerted on the blood vessels with the movement of the flap must also be considered. In general, movement and blood supply work countercurrent of each other. Just as in a flexible rubber tube, when tissue is stretched in order to close the primary defect, tension on the vessels will result in narrowing and ultimately the closure of the lumen if tension becomes too great. While this is a fairly minor consideration on the head and neck where blood supply is abundant, it is a major consideration on the trunk and extremities and in irradiated or heavily scarred areas where blood supply may be more tenuous.

FORCES OF CLOSURE

Despite many different techniques and variations in the planning and design of flap reconstruction, each flap repair shares a commonality regarding the forces that govern its closure. The ultimate closure of a flap is the result of four or more vectors of movement. First, the skin flap is moved into the primary defect; this movement defines the primary movement of the repair.¹⁵

The tissue surrounding the primary defect also moves inward toward the defect, creating secondary tissue movement. These two vectors are typically in opposite directions to one another.^{15,16} The flap itself and the skin surrounding the primary defect also undergoes stretch, creating two additional vectors of movement. The combination or the sum of these four vectors will ultimately define the wound closure tension across a repair's suture lines (Fig. 20-4). If all of these vectors are not appropriately accounted for, a repair may be inadequately sized to fill the primary defect, or flap failure could result secondary to necrosis or other complications. Higher wound-closure tension may also result in an increased risk of distortion of normal anatomic boundaries.¹⁵

Figure 20-4. The closure of a flap is the result of four vectors of movement. Primary movement is created as the flap is moved into the primary defect. The tissue surrounding the defect moves inward toward the defect creating secondary tissue movement. Both the skin of the flap as well as the skin surrounding the primary defect also undergo stretch, creating the final two vectors of movement. The sum of these four vectors ultimately defines wound closure tension.

The ultimate wound tension and final closure vector is also influenced by the property of skin extensibility (mechanical creep) and stress relaxation. These two properties are time-dependent factors of the skin in response to tension, and can alter the vectors of closure. Skin extensibility refers to the lengthening or stretching of skin secondary to the lengthening of elastic fibers when constant tension is applied. There are directional variants to extensibility, and they are found to be at a maximum along lines of maximum

extensibility in the skin. Thus repairs should ideally be planned parallel to relaxed skin tension lines, creating the vector of tension perpendicular to the repair and along a line of maximum extensibility, ultimately minimizing the appearance of the scar. An additional vector of flap closure, stress relaxation, also occurs as the skin undergoes creep. As the skin lengthens, the stress or tension across the wound or suture line decreases. While these two factors may ultimately influence the final vector of closure, they should not be used or relied upon during flap design.¹⁷ The composition of skin, specifically the dermis, and the presence of age-related changes, atrophy, or actinic damage will ultimately influence the four vectors of closure, increasing the ability of the skin to undergo not only primary and secondary movement but also stretching or lengthening in all directions (Table 20-3).

Table 20-3. Extensibility and Relaxation

Extensibility (Mechanical Creep)	Stress Relaxation
Lengthening or stretching of skin secondary to the lengthening of elastic fibers when constant tension is applied	As the skin lengthens, the stress or tension across the wound or suture line decreases

RESTRAINT

In addition to the forces involved in wound closure discussed above, a similar set of forces have been defined which serve to limit the primary motion of a flap. These factors serve as variants of *restraint*: negative vectors that work to counteract a flap’s primary movement.¹⁸

These vectors can be found in several different directions along a repair. The skin surrounding a raised flap exerts tension in the opposite direction of the new, desired movement of the tissue flap, creating *horizontal restraint*. The tissue underneath a flap, due to its connections to deeper structures in the skin, can exert *deep restraint*, a downward vector that may limit the desired movement of a flap (Fig. 20-5). Undermining around the flap pedicle, the wound base, and the surrounding skin involved in the repair may minimize the magnitude of this restraint. Extensive undermining, however, is not required, and may risk damage to critical structures and even impair blood

flow. Most of the benefits from undermining are seen within the first 1 to 2 cm out from the wound edge.¹⁷

Figure 20-5. (A) Prior to the incision of an advancement flap, the surrounding skin creates horizontal restraint. (B) Undermining a flap removes deep restraint, which is secondary to the flap's connections to underlying deep structures.

In flaps undergoing rotational movement, the pedicle, or attachment, creates a focus of *pivotal restraint* that can limit movement of the flap into the primary defect. The amount of pivotal restraint is also influenced by the elasticity of the skin and is magnified in thicker, less flexible skin and minimized in thinner, more elastic skin. This tethering can be seen in flaps such as rotation and transposition flaps (as well as many advancement flaps) that undergo pivotal movement, and must be taken into consideration when planning these repairs. Otherwise, the planned flap may not fill the primary defect, resulting in increased secondary movement, increased closure tension, and potentially distortion of neighboring free margins, anatomic boundaries, or flap-tip necrosis.

For rotation flaps, the leading edge of the flap can be extended to compensate for the rotational shortening caused by pivotal restraint. For transposition flap repairs, which involve two foci of pivotal restraint, the leading edge of the flap must be longer than the sides of the defect to avoid complications from pivotal restraint. Both of these modifications result in the necessity of removing a dog ear of redundant tissue during the repair because of the length discrepancy between sides; most importantly, however, this mitigates the risk of vascular compromise or anatomic distortion (Fig. 20-6).¹⁹

A

B

Figure 20-6. (A) A rotation flap is planned. The rotational movement of the flap creates a focus of pivotal restraint or rotational shortening. This limits the primary movement of the flap and the planned

flap does not completely fill the primary defect. (B) One can compensate for pivotal restraint by extending the leading edge of a rotation flap. This allows for full closure of the primary defect without unnecessary tension.

Redundant collections of skin or dog ears are often created during both flap repairs and fusiform closures due to the forced movement of tissue. Their presence creates obstructive restraint against primary flap movement as the extra tissue functions as a physical barrier, impeding the desired movement. The creation of standing cones is influenced by the presence of length discrepancies between wound edges, the required rotational angle of movement, skin elasticity, and the surface contour in the area of the repair. The pivot, or angle of rotation, and the size of the resulting standing cones are positively associated with one another; the larger the required angle of rotation, the larger the cutaneous deformity and thus obstructive restraint.¹⁵ Careful planning may decrease the significance of obstructive restraint; if standing cones of tissue were to develop, there are many surgical options which facilitate their removal and a proper closure, as detailed in [Chapter 9](#) (Fig. 20-7).^{15,20,21}

Figure 20-7. Compression of a standing cone deformity or dog ear provides a focus of obstructive restraint against primary flap movement as the extra tissue functions as a physical barrier impeding the desired primary movement.

FLAP TYPES: SLIDING AND LIFTING

Flap repairs may be classified in many ways, though when discussing their use for the repair of facial defects, it is straightforward to subdivide them into two categories, sliding or lifting, based on the overall tissue movement required (Table 20-4). The predominant movement in sliding flaps is direct translational movement of the flap into the primary defect. This creates a secondary defect, which typically has unequal wound-edge lengths, and is often closed with the assistance of removal of standing-cone deformities. The key, tension-bearing sutures are placed to close the primary defect. Both advancement and rotation flaps represent examples of sliding flap repairs.^{22,23}

Table 20-4. Sliding and Lifting Flaps

	Sliding	Lifting
Flap types	Advancement, rotation	Transposition
Movement	Direct translational movement	Lifting over bridge of normal tissue
Key suture placement	Primary defect	Secondary defect

Lifting flap repairs involve initial upward movement of the flap across a bridge of normal tissue to close the primary defect. As opposed to sliding flaps, the key, tension-bearing sutures are used to close the secondary defect. Transposition flap repairs, both single and multistaged, are examples of commonly performed lifting flap repairs.^{22,23}

All flaps must move from the donor site into the recipient site; this movement can be accomplished in various ways, depending upon the flap type. Irrespective of the flap type, movement is maximized through minimization of restraint. Any repair, including all flaps, should be designed to obey the following hierarchy; first, preserve or reproduce the functionality of the involved area; second, avoid distortion of free margins; third, maintain incisions within cosmetic unit or subunit junctions whenever possible; and finally, conform incisions to relaxed skin tension lines (Table 20-5). A thorough understanding of the dynamics and limitations of flaps will aid in planning flaps to satisfy the above criteria.

Table 20-5. Closure Hierarchy

I	Preserve function
II	Avoid free-margin distortion
III	Place incisions within cosmetic subunit boundaries
IV	Situate incisions in relaxed skin tension lines

DYNAMICS AND RESTRAINT OF ADVANCEMENT FLAPS

The advancement flap is one of the simplest flaps employed by the cutaneous surgeon. The fundamental purpose of all the advancement flaps is to achieve a greater degree of tissue movement than would be achieved by primary closure with undermining alone.²⁴ Commonly used advancement flaps in dermatologic surgery include the unilateral (O-U or O-L), bilateral (O-H or O-T), and V-Y (or island pedicle) advancement flaps.²⁵ Execution of these flaps involves the linear movement of tissue from donor to recipient site. With movement of the flap, one or more standing cutaneous deformities (dog ears, or standing cones) are created by compression of redundant skin during tissue movement.²⁶ For single tangent advancement flaps, these standing cones will form adjacent to the primary defect and at the terminus of the flap incision. For double tangent advancement flaps, the standing cones will develop at the terminus of each of the two parallel flap incisions. Double advancement flaps are created by simply mirroring two single advancement flap designs on opposite sides of the primary defect. The V-Y or island pedicle flap differs from the previously described advancement flaps in that it derives its vascular supply from a subcutaneous pedicle, and is devoid of all epidermal or dermal connections.

Due to the linear movement of advancement flaps, all flaps of this type are subject to horizontal, deep, and obstructive restraint. Horizontal restraint is released by making the flap incision. The longer the flap incision, the more horizontal restraint is released. In general, greater movement is achieved in areas of lax skin; thus, greater movement can be achieved if flap incisions extend into areas of tissue laxity. Therefore, whenever possible, the terminus of advancement flap incisions should lie in the areas of lax or mobile tissue

(Fig. 20-8). Recruiting this lax tissue reservoir allows lengthening (strain) with minimal force (stress), movement corresponding to Zone I on the stress–strain curve. Determination of an appropriate tissue reservoir should be completed early on in planning, as lack of tissue laxity available for advancement will undoubtedly adversely affect flap performance. A minimum requirement of all advancement flaps is to fully undermine the incised flap in order to release deep restraint and maximize movement. Undermining should include the undersurface of the flap and the area beneath the terminus of the flap incision, as this area must move toward the primary defect to maximize flap movement. Failure to release both horizontal and deep restraint simultaneously will result in a flap which does not function as anticipated. Excision of the standing cutaneous deformity adjacent to the primary defect eliminates this obstructive restraint in single tangent advancement flaps. In addition, excision of a standing cutaneous deformity at the terminus of the flap incision may also improve movement. While a curvilinear incision made along the limb of the flap may help redistribute tissue redundancy, eliminating the need for standing cone removal, this modification may also decrease the overall movement of the flap.²⁷

Figure 20-8. (A) A single tangent advancement flap is designed to repair a defect of the upper eyelid. The flap incision is made in order to reach the adjacent tissue reservoir in the temple. (B) Flap sutured into place. (C) Three-month follow-up.

DYNAMICS AND RESTRAINT OF ROTATION FLAPS

Rotation flaps comprise the second category of sliding flap repairs. These random pattern flaps are designed in a curvilinear configuration, which extends directly from the primary defect. One of the primary defect's wound

edges, therefore, becomes the leading edge of the flap.²⁸ The inherent rotational movement of these flaps redistributes the vector of tension along the wound. A semicircle flap is raised and rotated into the primary defect. The first key suture is then used to close the primary defect. By closing the primary defect, a secondary, crescent-shaped defect is created along the trailing edge of the flap. The length of the flap directly determines the ultimate shape and size of the secondary defect: The larger the flap, the narrower and longer the size of the secondary defect. Planning to allow advantageous placement and easy closure of the secondary defect is key to successful execution of rotation flaps (Fig. 20-9). The narrower the secondary defect, the less tension that is then required to close the surgical wound completely.²³

Figure 20-9. (A) Rotation flap designed to close a 4-cm defect of the lower eyelid and cheek. Note that the flap incision is designed to go above the level of the intercanthal line. This ensures that no portion of the secondary defect of the flap is beneath the lower eyelid, thus preventing downward

tension on the lower lid and subsequent ectropion with secondary defect closure. (B) Flap sutured into place without tension on the lower lid. Note that a Burow's graft was used to resurface a portion of the secondary defect. (C) Three-month follow-up with a good cosmetic and functional result.

Rotation flaps are often best suited for the closure of triangular defects, thus the creation of a triangular defect prior to initiation of reconstruction can help eliminate the typical Burow's triangle or dog ear which results along the inferior aspect of the primary defect as the flap is rotated into place. The arc of the rotation most effectively minimizes wound tension at an angle of 90 degrees from the axis of defect. Increasing this further has minimal effects on amelioration of wound tension.²⁹⁻³¹ When planning a rotation flap repair, the length of the flap should be approximately four times the width of the triangular primary defect, as this can avoid the removal of an equalizing Burow's triangle.²⁸

The concept of restraint also influences the success of rotation flaps. The impact of horizontal, deep, and obstructive restraint on the outcome of a rotation flaps is similar to that seen in advancement flaps. To minimize horizontal or lateral restraint, rotation flaps should be designed in such a way that the flap terminus reaches an area of increased skin laxity or a mobile tissue reservoir. The rotation flap also must be undermined to release its deep attachments, thus decreasing the deep restraint and allowing for adequate primary movement of the rotation flap. Standing cutaneous deformities, or foci of obstructive restraint, can develop at a few sites along a rotation flap's incision lines. Initial excision of a triangular standing cutaneous deformity at the inferior aspect of the primary defect will allow for increased primary movement. Standing cutaneous deformities can also be removed along any portion of the superior curvilinear incision to compensate for the length discrepancy between the two arcs and avoid obstructive restraint.

Pivotal restraint is a key factor in rotation flap design. The pedicle of the flap and its connections to the surrounding skin and structures define a maximum amount of rotation allowed by the flap, thus limiting the main primary movement of rotational flap repairs.

In order to compensate for the pivotal restraint of rotation flaps, two modifications are often employed: the leading edge of the flap can be extended beyond the defect, or a back cut can be made into the flap pedicle. The extension of the leading edge allows the flap terminus to completely

close the primary defect without placing significant tension along the key sutures. A back cut will also allow increased movement but does incur a risk of compromising or decreasing the vascular integrity of the flap. A back cut can also lessen the deep and horizontal vectors of restraint. Pivotal restraint is a function of the angle of rotation of the flap; larger angles of rotation result in a higher degree of rotational shortening. Pivotal restraint will also increase in areas of thicker, more immobile tissue, as it is a function of the local tissue characteristics. It is imperative that a surgeon plans to compensate for pivotal restraint prior to the initial incision, as it is much more effective to alter the surgical plan initially rather than relying on intraoperative adjustments when an improper closure is encountered.^{19,29}

DYNAMICS AND RESTRAINT OF TRANSPOSITION FLAPS

The main advantages of transposition flaps are their ability to tap into adjacent tissue reservoirs as well as redirect tension vectors during closure. Movement of a transposition flap includes the lifting of the flap over intact intervening skin from a donor to a recipient site. The primary vector of tension in transposition flaps is always borne across the terminal defect, the defect furthest from the primary defect, that is, the secondary defect for single-lobed transposition flaps, the tertiary defect for bilobed flaps, and so on. Transposition flaps undergo pivotal movement to reach the primary defect. The single-lobed transposition flap, including the rhombic flap and its modifications, as well as bilobed and trilobed flaps (which have a rotational component as well), are the most commonly used single-stage transposition flaps in dermatologic surgery.

By virtue of their movement, all single-stage transposition flaps are subject to horizontal, deep, obstructive, and pivotal restraint. In order to minimize horizontal restraint exerted by the surrounding tissue, it is essential to ensure that the flap is fully incised down to the plane of undermining. Movement, and thus successful execution, of this flap will be hindered by even a small dermal or muscular attachment that remains due to failure to fully incise the flap. In order to eliminate deep restraint, it is important to realize that the “true” flap (the area of the flap that rotates) includes the entire surface between the base of the standing cutaneous deformity and the

terminus of the flap. As with all other flap types, it is essential that the deep attachments at the terminus be released to allow for unrestrained movement. Preexcision of the standing cutaneous deformity that is formed in the execution of this flap type helps to reduce any obstructive restraint, and is often performed first. Pivotal restraint, leading to effective shortening of the flap, may be minimized by decreasing the angle of rotation of the flap. Minimizing pivotal restraint is an especially important consideration in thicker skin due to the likelihood of significant rotational shortening (Fig. 20-10). Anticipating pivotal restraint helps to inform the selection between single-lobed, bilobed, and trilobed transposition flaps, and thus must be considered in the early planning stages of reconstruction (Table 20-6).

Figure 20-10. (A) A trilobed flap is designed to repair a 1.5-cm defect on the nasal infratip. Due to the highly sebaceous nature of the tissue and the inherent risk of rotational shortening, the flap radius is oversized to account for pivotal restraint. (B) Flap sutured into place without distortion of alar-free margins. (C) Three-month follow-up with excellent nasal symmetry.

Table 20-6. Types of Flap Restraint and Their Management

Horizontal	Flap incision, ideally into an area of laxity
Deep	Undermining
Obstructive	Dog-ear (standing cone) removal
Pivotal	Extend leading edge; back cut in the pedicle

DYNAMICS AND RESTRAINT OF INTERPOLATION FLAPS

Interpolation flaps comprise a unique subset of transposition flap repairs. They involve the lifting and movement of tissue across normal skin that is uninvolved in the primary defect. As opposed to transposition flaps, the bridge, or stalk of tissue, is left in place for several weeks to allow for adequate neovascularization to take place between the flap and the primary defect. Therefore, these repairs require multiple stages before they are complete. The two most common types of interpolation flap repairs include the paramedian forehead flap and the melolabial or nasolabial interpolation flap. The Abbé flap, or lip switch flap, is another interpolation flap frequently used for full-thickness defects of the lips.

All interpolation flaps arise from a rich vascular pedicle, either axial or random in origin, involve donor sites that are distant and noncontiguous from the primary defect, and (generally) require two or more stages for completion.³² Regardless of whether the flap is considered random or axial in pattern, these flaps are derived from areas with a robust blood supply. This increased vascularity allows for the increased flap length without significantly increasing the risk of distal flap necrosis when compared with other types of flap repairs. Once the flap has been incised and elevated, the deep and horizontal restraint forces are minimal for interpolation flaps. Interpolation flaps, however, are still limited by pivotal restraint, as it is the flap pedicle that limits rotation of the tissue into the primary defect. This can be lessened by the construction of a narrow pedicle, made possible by the axial or robust vascular pattern that provides the support for these flap repairs, ensuring sufficient blood supply to the flap terminus (Fig. 20-11). While such repairs may be more involved than random pattern flaps, they

have proven to be safe and successful options for extensive defects on the distal nose.^{32–35}

Figure 20-11 . An islanded modification of the melolabial interpolation flap creates a more flexible pedicle thus minimizing the risk of pivotal restraint.

CONCLUSIONS

Understanding the principles of flap dynamics is a prerequisite for successful flap design and performance. These principles range from the basics of tissue stress and strain through the concepts of restraint in all of its forms. Many common errors in flap design are rooted in a less-than-thorough appreciation of the fundamentals of flap dynamics. Therefore, a comprehensive appreciation of the importance of these principles—especially the concepts of pivotal, horizontal, deep, and obstructive restraints, and how to mitigate them—is of critical value prior to embarking on independent flap design.

SUMMARY

- Advancement flaps are among the most frequently performed flaps in dermatologic surgery.

- These flaps may be conceptualized as a geometric variation of a linear closure, resulting in dog-ear redistribution and tension release.

Beginner Tips

- Advancement flaps may seem deceptively simple; handling of the displaced dog ears, however, requires a thorough appreciation of tissue dynamics.
- As with all flaps, advancement flaps lead to a significantly extended suture line compared with a linear closure. Therefore, attention to detail in suturing techniques is of vital importance to camouflage the scar as effectively as possible.

Expert Tips

- Combining advancement flaps with suspension (tacking) sutures may be very useful around free margins.
- Advancement flaps may be combined with other approaches such as grafts (typically Burow's grafts harvested from the dog ears), partial closures, and SMAS plication.
- Crescentic advancement flaps may obviate the need for secondary dog-ear removal.

Don't Forget!

- Excessive undermining may be unnecessary and may increase the risk of tissue ischemia.
- Always keep in mind the maximal flap length to pedicle width ratios when designing advancement flaps.

Pitfalls and Cautions

- Never force an advancement flap; while this design may seem most straightforward, some situations call for other approaches.
- Always tailor flap design to the individual patient; flap elevation and undermining in patients on aspirin or anticoagulants may increase the risk of hematoma formation.
- When in doubt, consider drain placement in these patients, even after meticulous hemostasis has been obtained.

Patient Education Points

- Patients should be warned prior to flap closure that they will have an incision stretching well beyond the initially visible defect.
- Explaining that the additional scar length will likely heal with a minimally visible line may go a long way toward patient reassurance.

Billing Pearls

- Flap repair codes (140XX series) include the excision component, so it is not appropriate to bill both an excision and a flap repair code simultaneously.
- Mohs codes may be submitted along with flap repair codes, though they may be subject to the multiple procedure reduction rule.
- When coding a flap, medical necessity is the ultimate arbiter of appropriateness.

CHAPTER 21 Advancement Flaps

INTRODUCTION

Local random pattern flaps are workhorse reconstructive options for cutaneous defects. Advancement flaps are conceptually the simplest local flaps and fall within the group of *sliding flaps*, in which tissue is moved directly into the adjacent defect without *lifting* it over interposed tissue. Unlike rotation flaps, pure advancement flaps do not create significant secondary defects, and the leading edge of an advancement flap is not typically restricted significantly by pivotal restraint.

PRINCIPLES OF ADVANCEMENT FLAP DESIGN

Advancement flaps may be conceptualized as modified linear closures, with one or both apical standing cones (dog ears) moved laterally to facilitate aesthetic or functional closure. When a free margin such as the eyelid or lip, or a cosmetic subunit junction, would be violated by a linear closure, advancement flaps may be utilized to direct the standing cones away from these natural boundaries (Fig. 21-1). Additionally, advancement flaps often camouflage scars by placing incision lines along natural creases or cosmetic subunit junctions.

Figure 21-1. Advancement flaps allow for displacement of standing cones when they may infringe on free margins or cosmetic subunit junctions.

Common locations for advancement flaps include the upper and lower cutaneous lips, the nasal sidewall, the infraorbital cheek and lower eyelid, the forehead and temple, the preauricular cheek, and the helical rim. Advancement flaps have also been described for nasal tip defects (e.g., East–West flap).¹ However, the relatively immobile skin of the nasal tip and proximity to free margins limit the utility of advancement flaps to relatively small defects in this location.

Tension vectors

In contrast with rotation and transposition flaps, advancement flaps do not significantly alter the *direction* or *magnitude* of the primary tension vector for wound closure. The direction in which the flap slides toward the defect is considered the *primary* tissue motion, and the countermovement of the surrounding tissue to meet the flap is considered *secondary* tissue motion (Fig. 21-2). For defects of the midline face, the primary motion is usually lateral to medial; for defects of the lateral face, the primary motion is usually inferior to superior. Tension typically runs in a single vector along the direction of primary and secondary tissue motions, similar to what is seen with a linear closure.

Figure 21-2. Closure with an advancement flap relies on the primary motion of the flap and the secondary motion of the surrounding tissue to meet the flap. Keeping the tension vector parallel to free margins helps to preserve their position.

The free margins of the eyelids, nose, lips, and ears are vulnerable to distortion from nearby advancement flaps.² To avoid distortion of the anatomic landmarks, advancement flaps are usually designed to orient tension vectors parallel to the free margins. However, in some cases, it is preferable to design a flap so that the main tension vector is oriented perpendicular to the free margin. Tacking sutures that anchor the undersurface of the flap to relatively immobile periosteum or the origins of underlying muscles may diminish or eliminate tension at the primary defect and prevent free-margin distortion. On the central face, superficial musculoaponeurotic system (SMAS) plication sutures may also decrease tension at the dermal edges of the primary defect.

The primary motion of the flap faces resistance from three main extrinsic forces: lateral restraint (whose vector runs opposite to the direction of primary motion), deep restraint from the host bed, and superior/inferior restraint of the adjoining skin tissue (Fig. 21-3).⁹ Lateral restraint causes the greatest restriction, and is dependent on the elasticity and mobility of the donor skin. Deep restraint from the host bed is the next most restrictive, and can be largely mitigated by undermining. Superior/inferior restraint is the least restrictive force, and may be diminished by extending the length of the flap as long as perfusion pressure remains intact. For a full discussion of flap dynamics, see [Chapter 20](#).

Figure 21-3. The resistance to flap advancement comes from three main extrinsic forces: lateral, deep, and superior/inferior restraint. Among these factors, lateral restraint directed 180 degrees away from the direction of flap advancement is of the greatest significance. Undermining largely mitigates deep restraint.

Standing cones

The standing cones (dog ears) created by an advancement flap may be handled in several ways. While the entire standing cone is often moved laterally in one or two directions (Figs. 21-4A and 25-4B), sometimes a portion of the standing cone is removed at the base of the flap, in a fashion similar to a partial linear closure. A small standing cone or a portion of a large standing cone can be “sewn out” using the rule of halves along the base of the flap (Figs. 21-4C and 25-4D). Alternatively, the standing cone may be removed in a crescentic fashion (Fig. 21-4E),³ especially along curved cosmetic subunit junctions, such as the vermillion cutaneous junction and the nasolabial fold/alar groove.

Figure 21-4. Several common methods exist to deal with the displaced standing cones. The entire standing cone may be moved laterally in one direction (A) or split in two directions (B). Alternately, “rule of halves” suturing may be used to handle the standing cone (C), or “rule of halves” suturing may be combined with excision of part of the standing cone (D). Finally, the standing cone can be handled with a crescentic excision (E).

Flap vascularity

As discussed in detail in [Chapter 20](#), flap survival depends on a reliable blood supply. The perfusion of blood through the vascular plexuses decreases as the distance from the feeding artery or arteriole increases. When the perfusion pressure is too weak to keep blood vessels patent, blood flow stops and necrosis ensues. The portions of an advancement flap most vulnerable to necrosis are the distal tip (since it has fewer blood vessels to nourish it and since it is most distant from the feeding artery or arteriole) and the portion of the flap sutured under the greatest tension (since the tension from the closure also results in compressive forces on blood vessels).

The ratio of the length of the flap to the width of its pedicle has a significant impact on perfusion. As a general guideline, random pattern flaps on the face can easily sustain a 3:1 length-to-width ratio, while those on the trunk and extremities may be best designed with a 2:1 ratio.^{4,5} These guidelines, however, are not absolute, as the robust facial blood supply may sustain flaps of significantly greater length-to-width ratios. Indeed, many flaps on the eyelid and helical rim⁶ are regularly executed with length-to-width ratios of 4:1 or greater. Moreover, at some point increasing the width of the flap pedicle fails to improve blood supply, as perfusion pressure may be insufficient to feed an excessively long flap.⁷

The anatomic plane of flap elevation also impacts the flap's vascular supply. Deeper undermining planes may incorporate larger caliber arteries with greater perfusion pressures, encouraging perfusion, though this must be weighed against the risk of damaging critical anatomic structures, such as branches of the facial nerve.

Ideal undermining planes for advancement flaps vary by anatomic location.⁸ For the majority of advancement flaps on the lateral face, the preferred anatomic plane is just above the SMAS, as this protects facial motor nerves, creates a flap of sufficient thickness to have a robust vascular pedicle, and permits clean and efficient flap elevation deep to the dermal and subcutaneous vascular plexuses (Fig. 21-5). On the central forehead, nose, and scalp, a sub-SMAS plane is usually preferred due to the relatively avascular nature of this tissue plane and the low risk for clinically relevant facial muscle weakness from cutting terminal motor nerve branches.

Figure 21-5. On the lateral face and neck, an undermining plane above the superficial musculoaponeurotic system (SMAS) preserves maximal flap vascularity while protecting facial motor nerves branches, which lie underneath the SMAS and innervate muscles from their lateral undersurface.

Wide flap undermining may decrease deep restraint, though it also may impair the blood supply by cutting vertically oriented perforating blood vessels that nourish the flap. Undermining should be performed carefully from the flap tip toward the pedicle only up to the point where sufficient movement is achieved. Additional undermining does not necessarily improve flap mobility because it does not influence the dominant restricting force of lateral restraint.⁹ Studies of tissue biomechanics have confirmed that wide undermining of advancement flaps does not add mechanical advantage or increase flap mobility.¹⁰

Altering the defect to optimize flap design and execution

Deepening the defect

When closing defects that arise after Mohs surgery, an initial consideration is whether the surgeon should deepen the defect to a uniform anatomic depth. Excision of tissue at the wound base often removes some obstructive restraint for wound closure, thereby facilitating wound-edge approximation. However, if deepening the defect may also risk functional deficit (i.e., facial nerve paralysis), it should be avoided. Deepening the defect to a uniform depth that corresponds to the anatomic plane for undermining facilitates efficient surgery and ensures that the tissue that “slides” into the wound matches the thickness of the defect.

Enlarging defects to camouflage the scar in cosmetic subunit junctions

While not always necessary or preferred, excising tissue between the surgical defect and a nearby cosmetic subunit junction may be helpful in

certain situations. Placing scar lines along cosmetic subunit junctions camouflages scars by hiding them in natural creases and shadows.^{11–13}

On the upper cutaneous lip, relaxed skin tension lines run radially from the vermilion–cutaneous junction, and horizontal scars in the middle of the subunit may be conspicuous. Extending a defect from the middle of the lateral cutaneous upper lip to the vermilion helps to hide the base of the advancement flap in the vermilion–cutaneous junction (Fig. 21-6). In contrast, on the forehead, the surgeon has several options to make incisions along cosmetic subunit junctions or along relaxed skin tension lines. The surgeon may opt to slide the flap along the relaxed skin tension lines (Fig. 21-7), the hairline, or the eyebrow. Wounds on the nasal sidewall may be extended inferiorly to hide the base of the advancement flap in the alar groove. The benefits of adhering to the subunit principle should be weighed against the sacrifice of healthy tissue and the creation of a larger defect requiring reconstruction.

Figure 21-6. Defect on the right upper cutaneous lip after Mohs surgery for a squamous cell carcinoma in situ. An advancement flap was designed. The remainder of the lip cosmetic subunit between the inferior margin of the defect and the vermilion–cutaneous junction was marked for removal to camouflage the scar along the vermilion–cutaneous junction (A). The 8-week postoperative result is shown (B).

Figure 21-7. Long-term result from a bilateral advancement with incisions along the horizontal relaxed skin tension lines on the forehead. Repair performed by an outside surgeon.

Suturing technique considerations

Unlike certain other local flaps, such as island pedicle flaps and bilobed flaps, advancement flaps are rarely associated with postoperative pin-cushioning. Moreover, the straight limbs of an advancement flap are often easier to camouflage along cosmetic subunit junctions. The surgeon should be careful to avoid hypereverting scars that are to be camouflaged in concave cosmetic subunit junctions, such as the nasolabial fold, as hypereversion of these areas may be associated with residual ridging. The base of an advancement flap is generally under minimal to no tension, so undesirable eversion in this location may take longer to settle (Fig. 21-8). To mitigate this

risk, suturing techniques may be adjusted accordingly, and simple buried sutures (that may encourage slight inversion) may be used in lieu of everting techniques such as the set-back suture or buried vertical mattress suture. If needed, suspension sutures or inverting techniques may be used as well; for a full discussion of tailored suturing approaches, see [Chapter 13](#).

Figure 21-8. An advancement flap was used to reconstruct this defect on the lateral suprabrow (A). The incision line used to displace the standing cone is typically under minimal tension. Eversion along this line was persistent at 8 months postoperatively and can take substantial time to resolve spontaneously (B).

Anchoring procedures and SMAS plication for periocular flaps

The lower eyelid is vulnerable to ectropion from vertical tension, even if the defect does not directly involve the eyelid margin.² To avoid eyelid malposition, the lower eyelid may be anchored to the periosteum of the lateral orbital rim for support (Fig. 21-9). Laterally based suspension sutures in periocular reconstruction advance the tissue around the eyelid defect to the lateral orbital rim.¹⁴ SMAS plication may be occasionally helpful to avoid eyelid malposition and counteract the weight of a flap or gravitational pull for periocular advancement flaps.¹⁵ The degree of SMAS lift may be as small as a lateral suborbicularis oculi fat (SOOF) elevation or as large as a

modified lateral midface lift, depending on the size of the defect and the individual patient's anatomy. When performed, these techniques are often executed in concert with a canthoplasty.

Figure 21-9. Defect photo (A) after resection of a tumor on the lateral canthus and lower eyelid. The wound was repaired with an O-to-T advancement flap (B). To prevent downward traction on the eyelid, an external canthoplasty and a SMAS lift were performed to elevate the midface and prevent eyelid retraction (B). The patient had excellent apposition between the globe and the lower eyelid postoperatively (C).

Preoperative preparation and patient counseling

It is most accurate to mark the position of cosmetic subunit junctions *prior* to infiltrating local anesthesia. Distortion from anesthesia may blur these anatomic boundaries and make accurate placement of incision lines more challenging. While drawing these preoperative markings, it is helpful to explain to the patient why lines are being drawn that extend away from the site of the defect. This may also assist with controlling patient anxiety.

As with any closure, setting realistic expectations prior to advancement flap closure may help maintain a healthy patient–physician relationship in the postsurgical healing period. Beyond the typical counseling for infection, bruising, swelling, and scar formation, several situations may warrant extra counseling. First, advancement flaps on the lower eyelid are occasionally complicated by prolonged postoperative edema that may take months to fully resolve. Second, incision lines that fall along natural grooves or creases camouflage well over time, but they may be noticeable in the early postoperative period, particularly if the wound edges are markedly everted. In general, tincture of time and the occasional use of intralesional steroids correct any residual eversion.

TYPES OF ADVANCEMENT FLAPS

Advancement flap may be categorized based on the number and locations of standing cones that are displaced due to tissue advancement. Thus, with two standing cones on the sides of the defect and (in a simplified example) two directions to move the standing cones, four potential basic advancement flap designs are available. Additionally, the crescentic advancement flap is a frequently utilized approach in dermatologic surgery as well.

Burow's wedge flap (O-to-L)

The O-to-L advancement flap, also known as a unilateral Burow's wedge flap, is perhaps the most common variant of advancement flaps used by dermatologic surgeons (Fig. 21-10). Here, one standing cone is moved laterally along the base of the flap. Common locations for this flap are the cutaneous lip, the nasal sidewall, the forehead, the suprabrow, the temple, the lower eyelid, and the mid cheek (Fig. 21-11). A step-by-step approach to this flap technique is demonstrated in Figure 21-12 .

Figure 21-10. O-to-L flap design (Burow's wedge flap). Unidirectional primary tissue movement and one standing cone displaced.

A

B

C

D

Figure 21-11. Common locations for an O-to-L advancement flap are the cutaneous lip (A—defect; B—9-month follow-up), the nasal sidewall (C—defect; D—2-month follow-up), the forehead (E—defect; F—5-week follow-up), and the lower eyelid (G—defect; H—9-month follow-up).

A

B

C

D

E

F

Figure 21-12. Flap design (A). The inferior standing cone was removed (B,C,D). Then the incision along the junction of the cheek and eyelid was performed (E), and the flap was undermined above the SMAS (F). The skin around the defect was undermined (G). The first key suture was placed at the

point of the highest tension (H,I,J). The remainder of the deep (K) and superficial sutures are placed, and the patient is instructed to open his mouth widely, open his eyes, and look up to place the lower lid under maximal stress and assess for ectropion (K). Six-week follow-up image is shown (L).

A-to-T flap

A frequently used technique, also known as an O-T advancement flap, the A-to-T advancement flap splits one standing cone into two smaller cones along the base of the flap (Figure 21-13). Often, the standing cone is at least partially sewn out by a “rule of halves” suturing technique (see Chapter 19) that may obviate the need for large displaced dog ears. This approach is frequently used on the forehead and lips. A step-by-step approach to this technique on a Mohs defect on the right upper lip, right philtral column, and nasal sill is shown in Figure 21-14.

Figure 21-13. O-to-T flap design. Bidirectional primary tissue movement and one standing cone displaced.

Figure 21-14. Defect after tumor removal (A). An O-to-T advancement flap with an M-plasty was designed to close the defect. First, the standing cones for the M-plasty were removed (B,C). The apices of the M-plasty were placed to either side of the peak of the vermillion-cutaneous junction below the

right philtral column (C). The incisions for the advancement flaps were made along the nasal sill (D,E), and the flaps were undermined above the SMAS overlying the orbicularis oris (F,G). The wound was then closed in a layered fashion (H,I,J), and her 3-month postoperative result with preservation of free-margin position is shown (K).

Unilateral advancement flap (O-to-U)

This classic unilateral advancement flap is often used for eyebrow defects, eyelid defects, and forehead defects (Fig. 21-15). The principal disadvantage of this advancement flap design is that the advancing edge of the flap may be quite distant from the vascular pedicle, depending on the degree of undermining. However, if the vascular supply is robust, successful results can be achieved even with high length-to-width ratios.

Figure 21-15. O-to-U flap design. Unidirectional primary tissue movement and two standing cones displaced.

A common variation of this approach is the helical rim advancement flap (Figs. 25-16 and 25-17). This technique is useful for even fairly large defects on the helix, and the robust blood supply available to this flap has been described.⁶

Figure 21-16. Schematic of helical rim advancement. **A.** A typical helical rim advancement flap. An incision is created along the anterior surface of the ear and carried into the lobule where a medial standing tissue cone is removed. The tissue is reflected off the cartilage and maintained on a posterior pedicle. The flap is advanced and the helical rim is approximated with eversion. A standing tissue cone is removed on the posterior surface of the ear. **B.** A chondrocutaneous advancement flap. Incision is carried out through cartilage and the flap is advanced and rotated into place. The inclusion of cartilage may be of greater benefit when the defect is higher on the helix or when more cartilage has been lost in the operative wound.

Figure 21-17. Defect and advancement flap design (A,B) with full-thickness incision planned through the helical rim for reconstruction. The 4-week postoperative result is shown (C,D).

The classic unilateral advancement flap may also be used in areas that are not traditionally approached with this technique, such as the cutaneous lip (Fig. 21-18).

Figure 21-18. A defect on the left upper cutaneous lip resulted from removal of a squamous cell carcinoma with Mohs surgery (A). An O-to-U type advancement flap was designed with planned resection of the remainder of the lip cosmetic subunit (*red arrows*) between the nasolabial fold and the vermilion–cutaneous junction (B,C). Result at 2-week postop (D).

Bilateral advancement flap (O-to-H)

The bilateral advancement flap, also known as an H-plasty, is formed by creating two opposing O-to-U unilateral advancement flaps (Fig. 21-19). The result is an H-shaped scar that is ideally masked within relaxed skin tension lines or along cosmetic subunit junctions. Prior to making incisions for the second pedicle of the flap, it may be prudent to completely undermine and

mobilize the first pedicle to assess if the second arm is absolutely necessary. The two arms of the flap may be sized differently depending on the degree and location of required tissue movement.

Figure 21-19. Bilateral advancement flap O-to-H design. Bidirectional primary tissue movement is seen and two standing cones are displaced.

Crescentic advancement flap

The crescentic advancement flap is a simple, yet powerful, variation of a unilateral advancement flap. Traditionally used along the alar crease and nasofacial sulcus, this technique is frequently employed for modestly sized nasal sidewall defects. This permits the surgeon to effectively hide incision lines in cosmetic subunit boundaries, and—importantly—as the curved crescents of tissue lengthen, this approach may obviate the need for dog-ear removal as well (Fig. 21-20).

Figure 21-20. A crescentic advancement flap is designed to close an operative wound adjacent to the nasal ala with the upper and lower limbs of the advancement falling along the nasofacial sulcus, alar crease, and nasolabial fold. The design is simple in appearance but deceptively complex. As the flap advances, the shorter crescentic limbs stretch out to meet their destination and dog ears are not produced. Crescentic modification of a bilateral advancement flap may avoid the need for the removal of standing tissue cones.

COMBINING ADVANCEMENT FLAPS WITH OTHER CLOSURES

Advancement flaps may be used in isolation or in conjunction with other closure types. Combinations of repair types are typically employed when a defect spans multiple cosmetic subunits or when complete wound closure with an advancement flap would place excessive tension on the leading edge of the flap. Advancement flaps may be combined with skin grafts (Fig. 21-21) as well as secondary intention healing (Fig. 21-22), and SMAS lifts (Fig. 21-23).

Figure 21-21. Clinical presentation of an invasive melanoma initially diagnosed as recalcitrant seborrheic dermatitis (A). Defect after removal with Mohs surgery with MART-1 immunostaining and closure design (B). Partial closure with bilateral advancement flap and repair of central glabella with a full-thickness skin graft (Burow's graft) to prevent medial eyebrow pull (C). Seven-month postoperative result (D).

Figure 21-22. Defect after two stages of Mohs surgery to remove an infiltrative basal cell carcinoma (A). Design of O-T type advancement flap along the nasal sill (B). Wound sutured closed with a small portion within the nasal cavity left to heal by secondary intention (C). The apical triangles were preserved. Three-month postoperative result (D).

Figure 21-23. A lateral canthal defect involving 30% of the upper eyelid and 50% of the lower eyelid (A). A tarsal conjunctival flap from the upper eyelid was sutured in place to form the posterior lamella

(B). The anterior lamella was re-created using a direct advancement flap which was anchored to periosteum, and a SMAS lift was performed (C). The patient had good eyelid contour and position immediately after closure (D).

COMPLICATIONS

Lower eyelid edema

Edema of the lower eyelid is frequently seen after advancement flaps are performed on the eyelids and upper cheeks (Fig. 21-24). Warning patients of this eventuality may help mitigate anxiety and distress in the postoperative period, especially as this process generally resolves spontaneously over a period of months.

A

B

C

Figure 21-24. Defect after removal of basal cell carcinoma on the medial cheek and lower eyelid after two stages of Mohs surgery (A). The wound was reconstructed with an O-to-L type advancement flap, and no immediate postoperative ectropion was present even with the patient placing stress on the anterior lamella by opening his eyes and mouth (B). At 10 weeks, he continued to have lower eyelid edema (C). This resolved spontaneously over the following 3 months, and he declined further in-office follow-up.

Disruption of cosmetic subunit junctions

A cheek-to-nose flap may bridge the concavity of the nasofacial sulcus as the wound contracts, unless the flap length is adjusted accordingly and tacking sutures are used to recreate the concavity. While this may be corrected with a secondary procedure, it is far better to appropriately design the flap *de novo* and utilize an appropriate-sized flap with tacking sutures, saving the patient the significant morbidity and cost associated with a secondary procedure.

On the lip, advancement flaps that require excision of the superior standing cone along the base of the nose may ablate the apical triangle and divert the nasolabial fold toward the lateral ala.^{16,17} If there is no alternative to preserve the apical triangle, patients should be counseled preoperatively that the nasolabial fold may appear to “dive into” the nasal sill as opposed to continuing seamlessly onto the nasal sidewall. The natural course of the nasolabial fold can be restored with a Z-plasty.

Displacement of free margins

Whenever an advancement flap is adjacent to a free margin, the surgeon must be careful to keep from “pulling” or “pushing” the margin out of position. To avoid “pulling” on a free margin, the primary tension vector for closure should be parallel to the free margin. “Pushing” may occur when the opposing sides of the advancement flap that come into apposition are significantly longer than the length of the original tissue that is being resurfaced, similar to the phenomenon that occurs with fusiform linear closures.¹⁸

Postoperative complications such as edema, bleeding, or tension can cause ectropion of the lower eyelid. Late ectropion is typically secondary to poorly designed flaps that “pull” on the lower eyelid (e.g., the tension vector for wound closure has a component that is oriented perpendicular to the eyelid margin), scar contraction, or insufficient replacement of the anterior lamella with an undersized graft or flap. Skin grafts and canthal tightening procedures are often used to repair ectropion. Intraoperative assessment of lower eyelid position may help to avoid ectropion. The surgeon can ask patients to open the mouth widely, open the eyes widely, and look up, a position that maximizes stress on the anterior lamella of the lower eyelid (Fig. 21-24). As edema secondary to local anesthesia may temporarily alter free-margin position during surgery, careful preanesthesia planning is of paramount importance.

Advancement flaps from the cheek for defects on the nasal dorsum or sidewall are a reliable option for reconstruction (Fig. 21-25). However, for defects that extend below the peak of the alar groove, advancement flaps from the cheek may result in superior displacement of the nasal tip and alar rim. For these defects, other reconstructive options should be considered to avoid free-margin displacement.

Figure 21-25. Defect with inferior edge above the peak of the alar groove (A). Advancement flap designed (B). Four-month postoperative result with preservation of the position of the alar rim (C).

“Bulldozing,” or the appearance of downward displacement of the lateral portion vermilion cutaneous junction (white line), may occur when an advancement flap along the white line does not account for the difference in the vertical position of the medial white line compared to the lateral white line (Fig. 21-26). Especially in patients with a larger slope to their vermilion–cutaneous junction (usually younger patients and women), an ill-planned advancement flap may bulldoze the vermilion inferiorly (Fig. 21-27). Anticipating this eventuality, a small wedge can be removed at the vermilion–cutaneous junction prior to closure, avoiding the need for a secondary revision procedure.

Figure 21-26. The geometry of upper lip bulldozing. The discrepancy between the vertical position of the medial white line compared to the lateral white line may lead to downward displacement of the lip.

Figure 21-27. Defect after removal of a basal cell carcinoma with two stages of Mohs surgery in a 31-year-old female. Note the relatively steep slope of her vermilion–cutaneous junction (A). Immediate postoperative appearance after advancement flap closure (B). Postoperative appearance at 5 months with “bulldozing” or “hooding” of the right lateral vermilion lip by the advanced tissue (C).

Textural differences

When an advancement flap is utilized to repair a defect, the advanced tissue typically has an excellent color and texture match to the native skin.

However, for defects bridging cosmetic subunits, advancement flaps may fill the defect with skin of a different texture, hair density, or thickness. In such cases, it may be helpful to thin the dermal component of the flap to match the thickness of the skin surrounding the defect.

CONCLUSIONS

Advancement flaps represent a versatile workhorse reconstructive approach, particularly for defects close to free margins. Appropriate design and execution require mastery of several key concepts, including appreciating the direction of the primary tension vector; handling the displaced standing cones; balancing local factors that impact flap vascularity; and deciding when to alter the defect prior to tissue advancement. Thoughtful incorporation of these concepts, while keeping in mind the fundamental principles of flap dynamics, results in predictably reliable outcomes.

Mary E. Maloney

Dori Goldberg

SUMMARY

- Rotation flaps recruit tissue via rotational movement around a pivot point and rely on tissue laxity adjacent to the surgical defect.
- Tension vectors can be dispersed variably across the arcuate path of the flap, and there are two areas where tissue redundancy becomes evident—the pivot point adjacent to the primary defect and the flap base at the end of the arcuate incision.

Beginner Pearls

- Pivot point redundancy can be removed as a standing cone either before (“triangulating” the defect) or after inset of the flap; flap-base redundancy can be redistributed by meticulous rule-of-halves suturing or removed as a standing cone.
- All rotation flaps are subject to rotational shortening and pivotal restraint—as the flap tip rotates inward to fill the primary defect, the arc length of the flap decreases, which can be solved by oversizing the flap.

Expert Pearls

- A backcut can further reduce pivotal restraint and assist in rotating the flap into place, though it also reduces the width of the pedicle and may compromise flap perfusion.
- Rotation flaps may be very useful on the nose; always keep in mind that the undermining plane should be submuscular.

Don't Forget!

- A double rotation flap comprising two traditional rotation flaps taking off from the opposite sides of the defect can be useful in areas of high tension.
- The comet (or dog-ear rotation) flap combines a primary closure of one end of the defect with the creation of a rotation flap from the tissue redundancy at the other end of the defect, and is particularly useful on the cheek.

Pitfalls and Cautions

- Large cheek flaps may result in ectropion; this risk may be reduced by using suspension sutures and oversizing the flap.
- Other complications include persistent lower eyelid edema and textural mismatch.
- The long secondary defects created by rotation flaps may lead to secondary tissue movement and free-margin compromise.

Patient Education Points

- Patients should be warned prior to flap closure that they will have an incision stretching well beyond the initially visible defect.
- Explaining that the additional scar length will likely heal with a minimally visible line may go a long way toward patient reassurance.

Billing Pearls

- Flap repair codes (140XX series) include the excision component, so it is not appropriate to bill both an excision and a flap repair code simultaneously.
- Mohs codes may be submitted along with flap repair codes, though they may be subject to the multiple- procedure reduction rule.
- When coding a flap, medical necessity is the ultimate arbiter of appropriateness.

CHAPTER 22 Rotation Flaps

INTRODUCTION

Rotation flaps are local cutaneous flaps that rely on tissue laxity adjacent to the surgical defect in order to accomplish closure. By design, these flaps recruit tissue via rotational movement around a pivot point. Rotation flaps are overwhelmingly random pattern flaps deriving blood supply from the dermal and subdermal plexuses, although on occasion they may carry axial vessels within the flap body.

In its most basic form, a rotation flap is created by extending a curvilinear or arcuate incision from the defect around a central pivot point. Inherent in this design is the formation of a broad pedicle and a desirable length-to-width ratio. These features contribute to reliable vascularity, viability, and an overall robust flap.

Rotation flaps differ from primary repairs or advancement flaps by the orientation of tension vectors. In primary repairs or advancement flaps, the tension vectors generally are directed perpendicular to the long axis across the wound, whereas in a rotation flap, the tension vectors can be dispersed variably across the arcuate path of the flap.

Rotation flaps in dermatologic surgery were first described by Konz and colleagues in 1975 for the repair of facial defects, but the use of rotation flaps dates back to 1842 as reported by Pancoast in the early plastic surgery literature.^{1,2} Since then, rotation flaps have been widely used in reconstructive surgery, and have been used for a variety of disease processes including pilonidal sinuses, decubitus ulcers, and cicatricial alopecia.³⁻⁵ In dermatologic surgery, rotation flaps have become a cornerstone of reconstruction, and their utility extends well beyond that of classically described rotation flaps with known eponyms.

FLAP DYNAMICS AND DESIGN

As with the design of any flap, it must first be determined which tissue reservoir will be recruited. A rotation flap is, by definition, a sliding flap. The tissue reservoir must be immediately adjacent to the defined surgical defect. When choosing a tissue reservoir, cosmetic subunits and potential distortion of free margins must be taken into consideration. Once the most appropriate reservoir has been identified, a curvilinear arc is extended from the wound around a central pivot point. Ideally, this arcuate incision may lie within a relaxed skin tension line, though this is not always possible. After the flap is incised, the flap, primary, and secondary defects are all widely undermined. The flap can then be rotated inward to fill the primary defect (Fig. 22-1).

Figure 22-1. Rotation flap geometry. (A) The primary surgical defect is denoted by the red circle. After determination of the tissue recruitment area, a sweeping curvilinear arc is carried away from the primary defect with a tangential start point (B) around a central pivot point (C). Tissue redundancy can be anticipated adjacent to the pivot (D), and oftentimes is removed preemptively as a standing cone.

At this point, there are two areas where tissue redundancy becomes evident—the pivot point adjacent to the primary defect and the flap base at the end of the arcuate incision. Pivot point redundancy can be removed as a standing cone either before (“triangulating” the defect) or after the inset of

the flap, and flap base redundancy oftentimes can be redistributed by meticulous “rule-of-halves” suturing or removed as a standing cone. This redundancy may or may not be significant, depending on the site and size of the defect.

A critical consideration in flap design is sizing of the flap. All rotation flaps are subject to rotational shortening and pivotal restraint—as the flap tip rotates inward to fill the primary defect, the arc length of the flap decreases. This is due to tissue restraint at the flap base. In clinical practice, two basic designs create the initial construct for most rotation flaps. These designs primarily differ in arc length of the flap tip and takeoff point. The arc of rotation for a standard rotation flap classically begins tangentially to the defect. With the forces of pivotal restraint, the flap tip is shortened upon rotation into the defect, and the tip must be advanced upward to completely fill the gap. As a result, a degree of tension is transferred to the flap tip, already the area most susceptible to necrosis. To combat this design flaw, Dzubow described a vertical offset or a “step-up” of the takeoff point of the flap.¹ In other words, this modification extends the length of the leading edge of the flap past the surgical defect, and can be thought of as “oversizing” the flap (Fig. 22-2). This approach allows the rotation flap to fill the defect under minimal tension on the flap tip. However, increasing the length of the leading edge of the flap will result in a larger secondary defect, which may be undesirable depending on the cosmetic subunit. This, in turn, will increase the tension across the secondary defect and must be accounted for. This exchange of tension between the two designs was nicely demonstrated by Lichon et al. *in vivo* using pig models and tension-measuring devices.²

Figure 22-2. Rotational shortening. (A) Rotation flap designed with “traditional” tangential takeoff angle. Pivotal restraint effectively shortens the flap tip as it moves through the arc of rotation, and places additional tension on the tip once the flap movement is complete. (B) Oversized rotation flap design overcomes rotational shortening but creates a larger secondary defect and potentially creates more tissue redundancy. Black arrows, primary flap movement; red arrows, vector of pivotal restraint; purple arrows, the greatest area of tension on secondary defect; purple circles, potential tissue redundancy.

Additional modifications to rotation flap features can aid in tissue movement and redirect tension vectors. The use of a backcut can further reduce pivotal restraint and assist in rotating the flap into place (Fig. 22-3). However, careful attention must be paid to the length of a backcut that is utilized. A backcut inherently reduces the width of the pedicle and may compromise flap perfusion. The overall length of the arc of the rotation flap is also a key component. Specifically, the arc length of rotation is inversely proportional to the closure tension across the secondary defect. This concept must not be overlooked when free margins are in close approximation of the planned secondary defect. Finally, the total angle of rotation should be considered. *In vivo* studies have shown that generally 90 to 135 degrees of rotation is appropriate. More obtuse angles of rotation do not improve, and may in fact hinder, tissue movement.³

Figure 22-3. Backcut modification. (A) A standard rotation flap is designed, but occasionally excess laxity is needed to complete the rotation. (B) A backcut is designed and incised. (C) This allows the completion of the rotation arc. (D) Final closure—the secondary defect of the backcut is closed in a V-Y fashion. Black arrow, primary flap movement; red arrows, tissue restraint vectors; purple circles, tension on final closure.

NOSE

Dorsal nasal rotation flap

In 1967, Rieger described the dorsal nasal rotation flap as a means for closing medium- to large-sized defects on the distal nose measuring up to 2 cm in diameter (Fig. 22-4).⁴ This flap utilizes tissue laxity on the upper nose and glabella. Marchac and Toth modified this flap by removing a standing cone vertically oriented from the superior aspect of the defect into the flap pedicle.^{5,6} Due to the rich blood supply of the flap, the authors argued that the flap was amenable to a shortened flap base in favor of greater mobility. Rigg described a variant of the dorsal nasal flap termed the heminasal flap that is particularly useful for smaller defects of the distal nose.⁷ The heminasal flap has the benefit of utilizing only a portion of the nasal skin. Depending on the location of the defect, the location of the free edge of the flap and the pedicle

can be adjusted. For example, the free edge of the flap would be oriented along the nasal midline for more medial defects, whereas lateral defects would be more readily repaired with the free edge directed along the nasofacial sulcus.

Figure 22-4. The dorsal nasal rotation flap. Note the use of a large backcut in the glabellar area to better mobilize the flap.

This flap and its modified versions are executed in a very similar fashion (Figs. 22-5 and 22-6). Initially, a broad sweeping incision is made from the glabella and carried downward past the medial canthus and along the nasofacial sulcus to the distal aspect of the defect. For purely midline defects, the pedicle may be based on either side of the nose. For defects that are even slightly lateral of midline, a contralateral pedicle is desired. A backcut of 30 to 45 degrees is made in the glabella to further aid in rotation. A general strategy for determining the height of the glabellar component of the flap is to measure 1.5 to 2 times the height of the nasal tip defect.⁸ The nasal component of the flap is then elevated just above the level of the periosteum and perichondrium. Undermining of the flap continues across the nasal dorsum to the contralateral nasofacial sulcus. When undermining the flap in the glabella, the level is superficial to procerus and corrugator supercilii muscles to prevent unnecessary disruption of motor function in this region. Once adequate hemostasis is obtained, the flap is rotated into place. The secondary defect in the glabella is typically closed first in a layered

fashion. As the flap is rotated, the glabellar portion of the flap usually becomes redundant and is trimmed. Careful planning and sizing of the flap as well as undermining of the surrounding tissue are necessary to prevent asymmetry. Oversizing of the flap is often utilized to prevent undesired distortion of the nasal tip. Additionally, a longer, broader arc of rotation can prevent pull on the contralateral medial canthus and ala.

Figure 22-5. Dorsal nasal rotation flap (“Reiger flap”)—defect of right nasal tip and supratip greater than 1 cm. A sweeping incision designed along the nasal sidewall and extending to the glabella with a backcut. The flap is rotated inferomedially, and the trailing edge of the flap is closed in a V-Y fashion.

Figure 22-6. Heminasal variant of dorsal nasal rotation flap—this flap was limited to one-half of the nasal dorsum and sidewall, achieving significant tissue recruitment from the ipsilateral nose and glabella.

There are several advantages of the dorsal nasal rotation flap. First, it provides good local tissue match for both color and texture. This flap also generally respects cosmetic subunit boundaries. Most of the suture lines fall within the glabellar furrows, the nasofacial sulcus, and the alar creases. Additionally, the robust blood supply derived from angular artery perforators contributes to excellent flap viability. Finally, this flap has the benefit of being a single-staged repair.⁷ The primary disadvantage of this flap is its large size, as much of the skin of the nose must be elevated to achieve adequate tissue movement and coverage.

Other nasal rotation flaps

A variety of other rotation flaps add to the cache of repairs for nasal reconstruction. A traditional rotation flap can be very useful in small- to medium-sized defects on the distal nasal sidewall, particularly those located just superior to the alar crease (Figs. 22-7 and 22-8). For such defects, a laterally based rotation flap utilizes tissue laxity from the sidewall superolateral to the wound, while also orienting the resultant standing cone along the alar crease. Similarly, traditional rotation flaps can be used to repair small defects of the middle-third of the ala located just below the alar crease. From the defect, incising laterally and inferiorly along the alar crease creates a rotation flap that is confined to the alar subunit. Once rotated medially, it provides excellent tissue coverage and match without adversely affecting the free margin of the alar rim.

Figure 22-7. Rotation flap repair of the supra-alar nasal sidewall with good cosmetic outcome. Although not represented in this repair, it is paramount to consider distortion of the ipsilateral alar rim when designing an adjacent rotation flap.

Figure 22-8. Medially based rotation flap for a lateral nasal sidewall defect. The glabella provides an ample tissue reservoir in this scenario within limited potential for webbing of the medial canthus.

Similar to a traditional rotation flap from the nasal sidewall, Hafiji et al. described a laterally based rotation flap from the nasal sidewall as an alternative to a bilobed flap for the repair of lateral nasal tip defects. Coined the “advancement and inferior rotation of the nasal sidewall (AIRNS)” flap, it incorporates advancement from the medial canthal region and rotation from

the nasal sidewall to repair defects of just over 1 cm. It also has the benefit of directing the standing cone deformity nicely along the alar crease.⁹

The spiral flap is another rotation flap elevated from the nasal sidewall that, in addition to simple rotation, can be utilized to repair defects involving or just below the alar crease (Fig. 22-9). This flap utilizes the relatively narrow flap tip folded back upon itself allowing preservation of the alar crease. As described by Mahlberg et al., this flap is useful for reconstructing defects of the alar groove and alar body of 5 to 15 mm in diameter.¹⁰ Not only does this flap offer the benefits of a single-stage repair with excellent local tissue color and texture match, it also reliably recreates the alar groove. Careful attention must be paid to preserving a broad pedicle, as there is a tendency when designing this flap to increase the length-to-width ratio which may predispose it to distal tip necrosis. This can be done by designing the flap as a logarithmic spiral as opposed to a classic Archimedean spiral.

Figure 22-9. Spiral flap—the spiral flap is a useful repair option for small defects of the superior ala. The leading tip of the flap is folded upon itself, allowing for accurate recreation of the alar groove. Caution must be taken to avoid undue tension on the tip as it is particularly susceptible to necrosis and strangulation.

A novel medially based rotation flap was reported by Bryan et al. for small- to medium-sized defects of the middle-third of the alar crease. Dubbed the “wave” flap, it shares elements of both a medially based hemi-nasal rotation flap and the spiral flap. Like a medially based hemi-nasal flap, it touts a broad pedicle and practicality for lateral nasal defects. Yet, similar to the spiral flap, the distal tip is turned back onto itself and cosmetically recreates the alar crease. One benefit of this flap over the spiral flap is that

the majority of its incision lines are camouflaged within the nasofacial sulcus.¹¹

Similar to the spiral and “wave” flaps, the “shark” island pedicle flap also takes advantage of rotating a portion of the flap back on itself to help recreate the alar crease (Fig. 22-10). It is particularly useful in reconstructing combined alar and medial cheek defects. This flap can be thought of as having two distinct components. The trailing portion of the flap is very similar to a traditional V-to-Y island pedicle flap. It is a random pattern flap of a long triangular shape oriented along the nasolabial fold that derives its blood supply from perforators of the angular artery. To this traditional island pedicle flap, the shark flap adds a leading portion that extends around the defect both superiorly and proximally. This small isthmus is a myocutaneous flap incorporating fibers of the levator labii superioris and should be designed to be the same width as the alar portion of the defect. As the trailing portion of the flap is advanced and the secondary defect is closed behind it, the leading portion is rotated between 90 and 180 degrees back on itself. This creates an inverted standing cone and suture line that create the alar crease.¹²

Figure 22-10. Shark-island flap—a variant on the spiral flap which recruits from the medial cheek and nasolabial fold. Again, tip necrosis is a concern, and measures to avoid excess tip tension are paramount to success.

The Peng flap, later modified by Rowe, is both a bilateral rotation flap and a direct advancement flap that recruits tissue from both nasal sidewalls and the glabella, respectively (Fig. 22-11). It is useful for nasal tip defects or defects straddling the cosmetic subunit boundary between the nasal tip and distal nasal dorsum of up to approximately 2 cm.^{13,14} Incisions are made from the medial canthus inferiorly along the nasofacial sulcus to the distal aspect

of the defect. The bilateral flap is then undermined and elevated deep to the nasalis muscle and then rotated medially to meet each other. A standing cone deformity is removed superiorly along the nasal dorsum. A more recent modification advocates for incising the distal portion of the flaps along the alar crease to better hide suture lines within subunit boundaries. Additionally, the cheeks can be advanced bilaterally to assist in the closure of the secondary defect with the removal of crescentic standing cone deformities along the alar crease as needed.¹⁵

Figure 22-11. The Peng flap.

EYELID AND INFRAORBITAL REGION

Large rotation flaps recruiting tissue laxity from the temple and cheek have been used to close surgical defects of the lower eyelid for nearly a half century. In 1966, Mustarde initially described a large rotation flap where a long, sweeping incision is made laterally along the lower eyelid–cheek junction, coursing superolaterally onto the temple and then inferiorly along the preauricular cheek.¹⁶ Coined the “Mustarde flap,” this reconstructive option has proved to be useful for large defects of the medial cheek and lower eyelid (Fig. 22-12). In 1970, Tenzel described a semicircular rotation flap from the temple of similar design and movement. This flap also incorporated the orbicularis oculi muscle and was intended for repair of full-thickness defects of the central or lateral lower eyelid.¹⁷ The movement of the Tenzel flap is further aided by a lateral canthotomy and cantholysis. Wounds up to two-thirds of the width of the lower eyelid can be repaired with this method.

Figure 22-12. Classic cheek rotation “Mustarde” flap—this classically described rotation flap is useful in the repair of large medial lower eyelid and upper medial cheek defects. A long, sweeping incision along the inferior eyelid, and extensive undermining is performed. Immediate postoperative and long-term postoperative results are shown as well with excellent cosmetic results. Redundancy along the nasofacial groove usually requires removal as a standing cone. Postoperatively, eyelid edema and lack of sensation are common findings.

As with many other rotation flaps, both of these flaps utilize advancement in addition to the primary motion of rotation. The tension vector along the leading free edge of the flap is oriented medially, while tension on the trailing edge is directed superiorly and laterally toward the temple and preauricular cheek. Very little tension is directed inferiorly, minimizing undesired distortion of the free margin of the lower eyelid. As stated previously, the length of the arc of any rotation flap is inversely proportional to the tension across the secondary defect. The long incision lines of these flaps further ensure minimal tension across the secondary defect and mitigate

the potential for ectropion. However, Mustarde himself recognized that large rotation flaps from the cheek have a tendency to sag over time given the added tissue bulk carried forward onto the lower eyelid.¹⁸ He advocated for the use of both deep tacking sutures and septal cartilage grafts to support the lower eyelid.

Numerous modifications to these basic designs have been described. The use of a Z-plasty at the lateral aspect of these flaps has been advocated as a means to push them medially. This effectively serves to resist the natural tendency of the tissue to recoil laterally. Additionally, inverted forms of the semicircular flap have been shown to be useful in repairing similar defects of the upper eyelid.¹⁹ Rao and Frank described a modification of the Mustarde flap which is helpful for repair of medial eyelid defects. It incorporates the standing cone typically created inferior to the defect as a Burow's graft to repair the noneyelash-bearing margin medial to the lower lacrimal punctum.²⁰ Purely cutaneous defects of the lower eyelid are very amenable to repair with a modification of Tenzel's semicircular flap. The principle design and tissue movement are identical to the original flap and they still require a superior arcuate extension to avoid unwanted secondary motion of the eyelid inferiorly. However, this flap modification is cutaneous only, being elevated above the level of orbicularis oculi, whereas the flap was musculocutaneous in its initial description.

Large temple and cheek rotation flaps are not without shortcomings. As mentioned, the primary concern with these flaps is support of the lower eyelid and prevention of downward tension that may result in ectropion. Both oversizing of the flap with broad superolateral arcuate incisions and the use of suspension sutures helps combat this potential pitfall. The Mustarde flap particularly relies on laxity from the preauricular cheek. If this laxity is not present, unwanted tension may occur with rotation and predispose to distal flap necrosis.¹⁹ Additionally, long-lasting eyelid edema is common owing to the disruption of the local lymphatic system. Finally, textural mismatch of the thick skin of the cheek and the thinner skin of the eyelid can also present challenges. This may be compensated for with appropriate thinning of the flap edge and careful suturing technique.

SCALP

Rotation flaps are particularly well suited for reconstruction of defects of the scalp, as limited intrinsic tissue mobility is often encountered. Though traditional single-arm rotation flaps are adequate in many circumstances, at times the added tissue recruitment from additional opposing rotation flaps may be required. A double rotation flap comprised two traditional rotation flaps taking off from opposite sides of the defect can be useful in areas of high tension. The opposing flaps are undermined in the subgaleal plane and rotated toward each other but in the same clockwise direction around the wound. The advancing edges of the flaps then meet together in the center of the defect (Fig. 22-13).²¹ When sutured in place, the resultant incision lines form a “Z,” thus explaining its common moniker of an “O to Z flap.” Though used infrequently, triple rotation flaps are noted in the plastic surgery literature for reconstructing large scalp defects. Specifically, Bardach described a technique that incorporates three opposing rotation flaps with backcuts.²² In addition to repairing surgical defects, these flaps can be used to correct areas of cicatricial alopecia.²³ Regardless of which rotation flap is employed on the scalp, all offer several advantages. Recruitment of local hair-bearing skin provides excellent match in color, texture, and hair density, and these flaps are relatively easy to elevate owing to the bloodless subgaleal plane of dissection. The primary disadvantage of either a double or triple rotation flap is the sheer quantity of incision lines created. However, the cosmetic impact may be minimal in this location if hair can be used to conceal these lines.

Figure 22-13. O-to-Z rotation flap of the scalp—large defects of the scalp can be closed with opposing rotation flaps in a “Z” orientation. Repair shown with good results and minimal distortion of surrounding free margins.

CHIN

Both midline and lateral chin defects are very amenable to repair via rotation flaps. This, in large part, is due to the contour of the chin, specifically the downturned semicircular shape of the mental crease in many individuals. Single-armed, traditionally designed rotation flaps are particularly suited for laterally based defects on the chin. These flaps are elevated above the mentalis muscle, and the long arcuate incision line is camouflaged neatly within the mental crease. Defects ranging from 2 to 3 cm can be repaired with excellent cosmesis.²⁴ Midline chin defects near the mental crease may be more appropriately reconstructed with a double, bilateral rotation flap. Nearly mirror image flaps are designed, again with the arc of rotation hidden in the cosmetic boundary separating this area from the cutaneous lip. As opposed to the O to Z flap, in this area, bilaterally symmetric flaps are rotated in opposite clockwise directions. The leading edges of the flaps meet in the midline and sutured together. A standing cone deformity is formed immediately inferior to the defect and requires extirpation.

CHEEK

Given the excellent tissue mobility on the cheek, most small- and medium-sized wounds are readily repaired in a primary fashion. However, larger surgical defects or those located near anatomic free margins may benefit from repair with rotation flaps. Large wounds of the preauricular cheek or inferior temple can be nicely closed with broad, medially based rotation flaps utilizing tissue laxity from the lower cheek and neck ([Figs. 22-14 through 22-16](#)). These flaps are undermined at the level of the superficial subcutaneous fat. The use of a backcut can aid in the rotation of these flaps or a standing cone deformity can be removed posteriorly around the earlobe to add a component of advancement to their movement. One advantage of this design is that it conceals many of the incision lines along the hairline and within skin folds of the preauricular cheek.

Figure 22-14. Rotation flap repair of a lateral cheek defect. Given the size of the defect, tissue recruitment from the ipsilateral jowl and submental skin is required. The defect size was narrowed first with a superior standing cone.

Figure 22-15. Large defect of the central cheek closed with a laterally based rotation flap. Note that the standing cone is oriented parallel to the nasolabial fold for optimal cosmesis.

Figure 22-16. Very large centromedial cheek defect. A large, laterally based rotation flap is designed to recruit from the lateral cheek, jowl, and submental skin. Once again, the inferior standing cone is

placed within the nasolabial fold to preserve the cosmetic subunit.

Defects on the superior cheek that are more medially located can be repaired with similarly designed inferolaterally based rotation flaps. Also undermined in the superficial subcutaneous fat, these flaps are rotated superiorly with the long arc of rotation oriented along the nasofacial sulcus. A flaw inherent in this design is the propensity to pull inferiorly on the lower eyelid and create a potential for ectropion. A recent small case series demonstrated that superomedial anchoring of such flaps to the periosteum of the nasal bone or medial maxilla resulted in no occurrences of ectropion.²⁵

The comet flap or dog-ear rotation flap, though useful in a variety of locations on the head and neck, is particularly useful on the cheek. This repair combines a primary closure of one end of the defect with the creation of a rotation flap from the tissue redundancy at the other end of the defect. After it is determined which end of the wound would be optimally closed in a primary fashion, the standing cone deformity is excised and an intermediate-layered closure is performed to a point at which further closure is not permitted due to excessive tension. The rotation flap is then designed to maximally utilize the tissue redundancy of the standing cone at the opposite end of the wound. The length of the arcuate incision of the flap should be approximately equal to the length of the remaining wound edge to provide for adequate rotation with minimal tension across the secondary defect.²⁶

LIP

Medium-sized defects of the upper cutaneous lip can be nicely reconstructed with a rotation flap elevated just medially to the nasolabial fold (Figs. 22-17 through 22-19). The long arc of rotation is incised along this cosmetic boundary separating the upper lip from the cheek, and the flap is then undermined above the orbicularis oris muscle. The incision line may be extended as far inferiorly as necessary to achieve adequate rotation without distortion of the commissure and vermillion. If required, a standing cone deformity angled medially can be removed around the commissure onto the lower cutaneous lip to prevent unwanted tissue movement. When rotated into position, a standing cone deformity must be removed inferior to defect. If the defect approaches or involves the apical triangle, the flap should be designed

and rotated in such a fashion as to recreate this important cosmetic subunit. Fullness of the upper lip and increased show of the vermillion are common in the immediate postoperative period, but this resolves within a week or two in an overwhelming majority of cases. A recent case report demonstrated excellent cosmetic outcomes for defects of 1 to 2 cm in diameter on the lateral upper cutaneous lip.²⁷

Figure 22-17. Defect of the right upper cutaneous lip–nasolabial fold repaired with a rotation flap. (A) Preoperative appearance. (B) Postoperative appearance.

Figure 22-18. Rotation flap of the lateral upper cutaneous lip (“Hatchet flap”). Note the rotation flap is designed such that the rotational arm of the flap recreates the nasolabial folds and the standing cone lines within the vertical perioral furrows.

Figure 22-19. Left upper lip rotation flap involving the vermilion border. (A) Preoperative appearance. (B) Postoperative appearance.

A similar flap that recruits tissue from the medial cheek has been effective in closing large defects of the cutaneous upper lip. This technique involves creating a template of the entire upper cutaneous lip subunit, to include the apical triangle, from the unaffected side and transferring it to the medial cheek of the affected side. The flap is then incised, maintaining an inferiorly base pedicle and undermined superficial to the orbicularis oris muscle. Once rotated into place, the flap recreates the entire upper cutaneous lip lateral to the philtral column. The lateral border of the flap recreates the nasolabial fold. Finally, the secondary defect on the cheek is repaired primarily.²⁸

FOREHEAD AND TEMPLE

The cosmetic boundaries of the frontal and temporal hairlines are well suited for hiding the long arcuate incisions created by rotation flaps. Traditional single-arm rotation flaps and double rotation flaps both have utility in these anatomic locations (Figs. 22-20 and 22-21). Asymmetric double-opposing flaps, one arm of which rotates while the other arm advances, have been shown to be highly effective for reconstructing defects on the temple, mid-forehead, and along the hairline. A recent series demonstrated good cosmesis without any alteration in eyebrow position in defects ranging from 3 to 30 cm.²⁹ Bilaterally symmetric double rotation flaps can also be effective for repair of defects along the hairline. Similar in design to the flap previously described in this chapter for defects on the chin, the long curved incision

lines frame the forehead creating two similarly shaped rotation flaps on either side of the defect. These flaps are rotated toward each other and the leading edges are sutured together along the midline after removing a small standing cone deformity inferiorly.

Figure 22-20. Large defect of the lateral forehead involving the lateral eyebrow. A rotation flap is designed to recruit tissue laxity from the temple—an ample reservoir.

Figure 22-21. Another rotation flap repair of the lateral eyebrow with good cosmetic outcome.

EAR

Though typically not considered a standard reconstructive option on the ear, rotation flaps may be employed to repair few, appropriately selected defects (Fig. 22-22). Specifically, defects of the antitragus may be aptly located for recruiting tissue laxity from the adjacent lobule. A flap with a superomedially based pedicle and an arc of rotation along the curvature of the scaphoid fossa can be rotated to repair defects in this location.

Figure 22-22. Rotation flap repair of the antitragus of the ear. Tissue laxity was recruited from the lobe in this situation.

COMPLICATIONS AND MANAGEMENT

Rotation flaps are susceptible to many of the same pitfalls that affect other types of flaps. The potential for postoperative bleeding is ever present in dermatologic surgery. A thorough preoperative evaluation to include the patient's use of anticoagulants is critical in identifying those at risk for this complication. Careful attention to intraoperative hemostasis, especially beneath the flap, is of the utmost importance, as a newly inset flap forms a potential space for hematoma formation. Bulky pressure dressings are another key component of preventing bleeding in the postoperative period.

Should persistent bleeding continue beneath the flap during the postoperative period, a true hematoma may develop. Within the first 24 to 48 hours following surgery, hematomas should be evacuated to ensure the greatest chance for flap survival. If the hematoma is not yet organized, attempts can be made to remove the blood with a syringe and 18-gauge needle. However, it is likely that the sutures will need to be removed and the hematoma physically evacuated while also irrigating the wound. This additionally offers the opportunity to visualize and address the source of bleeding, a critical step if the hematoma seems to be increasing in size. Once the wound bed and base of the flap are clean and dry, the flap may be resutured in place. Outside of the first 2 days postoperatively, hematomas are more likely to be organized and less amenable to evacuation. Not only do hematomas create pressure that may compromise flap perfusion, they also significantly increase the risk of wound infections that may adversely affect

flap viability. Thus regardless of the time following surgery, the presence of a hematoma is an indication for prophylactic antibiotics, as hematomas serve as a nidus of infection.

Complications that are unique to rotation flaps derive from the design and tissue movement of these flaps. As stated previously, rotational shortening is inherent in the expected movement of rotation flaps. When unaccounted for, rotational shortening can produce excessive tension on the leading edge of the flap. This may result in dehiscence of the wound or flap ischemia and necrosis along this edge. Unnecessarily high tension due to rotational shortening may be combated by increasing the length of the leading edge of the rotation flap beyond the defect. Also, wide undermining of the flap and the surrounding tissues further minimizes this risk.

In most cases, the geometric design of rotation flaps helps to ensure robust perfusion. One instance in which this blood supply may be compromised is with the use of a backcut to relieve pivotal restraint. When performing a backcut, the dermatologic surgeon must take care not to overly narrow the pedicle. Maintaining a length-to-width ratio of no more than 3:1 mitigates this risk.

Finally, rotation flap may also be complicated by altering the position of free margins. The long arcuate incisions often created by these flaps result in long secondary defects. It is important to be cognizant of the course of these secondary defects, especially when in close proximity to free margins. To varying degrees, there will always be secondary movement of the surrounding tissue to close the secondary defect. While it is true that increasing the length of the arc of rotation will decrease tension across the secondary defect, this must be weighed against extending the secondary defect to an anatomic location where a given amount of secondary tissue movement is unacceptable.

CONCLUSIONS

The rotation flap is a workhorse in the reconstructive toolbox of the dermatologic surgeon, and can be employed in a wide range of anatomic locations. As with many other random pattern flaps, the rotation flap has the advantage of good local tissue match with regard to texture, thickness and presence of adnexa. It is a reliably robust flap owing to its broad pedicle

inherent in its basic design. Generally, this flap is conceptually and technically simple to execute when proper planning and design considerations are accounted for. The modern dermatologic surgeon must be prepared to approach every surgical defect as unique. There is not a single “cookie-cutter” repair that is appropriate for all wounds of a given location. Often, an innovative combination closure is required incorporating a blend of flaps, grafts, primary closure, or second intention healing.

Jeremy R. Etzkorn

Joseph F. Sobanko

Christopher J. Miller

SUMMARY

- With transposition flaps, the position of the main tension vector is changed from the primary defect to a more ample adjacent tissue reservoir, and the elevated flap is transposed under little to no tension.

- The ability of transposition flaps to push tissue into the defect by redirecting tension vectors perpendicular to the primary closure direction, coupled with their ability to close a defect using a smaller total surface area than sliding flaps (and the possible added benefit of a broken-up repair line), make these flaps particularly useful for larger facial defects.

Beginner Pearls

- The pinch test may be useful to assess both the primary wound and nearby tissue reservoirs.
- Visualizing a rhombic flap as a rotation flap with a large backcut helps illustrate the consequence of pivotal restraint on flap movement.

Expert Pearls

- The takeoff point can influence flap vascularity and length, and is usually at the midpoint of the defect.
- The nasolabial single-lobed transposition flap is useful for reconstructing defects of the ala, though this flap can appear thick and pincushion without a precise undermining plane and tacking sutures to recreate the alar groove.

Don't Forget!

- The curved lines that result from most transposition flaps require meticulous suturing, as they rarely fall along cosmetic subunit junctions or relaxed skin tension lines. This attention to detail is particularly critical for successful execution of flaps on sebaceous skin, such as the distal nose.
- Taking off from the long axis of an asymmetric defect requires a greater arc of rotation and flap length, which both threaten the flap's blood supply. Distal takeoff points narrow the pedicle and compromise the blood supply.

Pitfalls and Cautions

- Pincushioning, or trapdoor deformity, may occur with transposition flaps, especially on the nose. Several etiologies have been suggested, such as excessive flap thickness, inadequate undermining, and circumferential wound contraction. Strategies to minimize pincushioning include appropriately sizing the flap, careful suturing of all anatomic layers, and closing any dead space under the flap. If intralesional corticosteroids do not resolve pincushioning, surgical thinning may be necessary.

Patient Education Points

- When recruiting tissue from distant sites, transposition flaps may not match the contour, texture, and hair density of the defect. Surgeons may counsel patients when additional procedures, such as staged surgery or hair removal, are anticipated.
- Transposition flaps that span multiple facial subunits may ablate cosmetic subunit junction lines. Patients may be prepared for the possibility of staged reconstruction to restore a concave subunit junction, such as the alar groove or melolabial fold.

Billing Pearls

- Flap repair codes (140XX series) include the excision component, so it is not appropriate to bill both an excision and a flap repair code simultaneously.
- Mohs codes may be submitted along with flap repair codes, though they may be subject to the multiple-procedure reduction rule.
- When coding a flap, medical necessity is the ultimate arbiter of appropriateness.

CHAPTER 23 Transposition Flaps

INTRODUCTION

Transposition flaps are often useful when tension at the primary defect precludes side-to-side closure or the use of sliding flaps, such as advancement or rotation flaps. To transpose means to switch positions, which aptly describes the flap's essence, as the position of the main tension vector is changed from the primary defect to a more ample adjacent tissue reservoir, and the elevated flap is transposed into the primary defect under little to no tension. Common transposition flaps include the rhombic (single-lobed), bilobed, and trilobed flaps, though the latter two flaps, in particular, involve a significant rotational component.

The ability of transposition flaps to push tissue into the defect by redirecting tension vectors perpendicular to the primary closure direction, coupled with their ability to close a defect using a smaller total surface area than sliding flaps (and the possible added benefit of a broken-up repair line), make these flaps particularly useful for larger facial defects.

PRINCIPLES OF TRANSPOSITION FLAP DESIGN AND EXECUTION

Using the pinch test to assess the primary wound for flap selection

Pinching, or squeezing together the primary wound edges, is a simple strategy to guide flap selection. If pinching easily approximates the wound edges, then side-to-side closure or a sliding advancement or rotation flap will usually be possible (Fig. 23-1). If pinching cannot approximate the wound edges

because of excessive tension or anatomic distortion from pulling or compressing free margins (e.g., eyelids, distal nose, lips), then a transposition flap may be useful to transfer tension to and recruit tissue from a more generous adjacent reservoir.

Figure 23-1. Pinching the primary wound edges guides flap selection. A linear closure or sliding flap is usually possible if the wound edges are easily approximated. If pinching the wound edges causes excessive tension or free-margin distortion, a transposition flap may be useful to transfer tension to and recruit tissue from an adjacent reservoir.

Using the pinch test to identify a donor tissue reservoir

After determining that direct closure of the primary wound is not possible, the pinch test can identify a suitable donor site for a transposition flap (Fig. 23-2). If the skin immediately adjacent to the wound pinches easily and without anatomic distortion, a single-lobed rhombic flap may be possible. If the skin adjacent to the primary wound is too tight, then the pinch test may identify a sufficiently lax tissue reservoir more remote from the primary wound. A bilobed or trilobed flap may be necessary to reach a distant reservoir.

A

B

C

D

Figure 23-2. A suitable tissue reservoir for a transposition flap is identified using the pinch test. For this defect on the preauricular cheek, tissue reservoirs located posteriorly (A) and superiorly (B) lack sufficient volume, laxity, and vascularity. The anterior tissue reservoir (C), while ample, may lead to

anatomic distortion. An inferior donor site (D) pinches easily without anatomic distortion and would be ideal. In order to reach this donor site, one or more lobes may be needed.

Assessing a wound on the distal nose illustrates the pinch test application. If pinching the tight, adherent distal nasal skin fails to approximate the wound edges, alters the position of the free margin, or compresses the nasal cartilages, then a transposition flap is considered. The pinch test is then applied to surrounding skin to identify a donor site. The skin of the nasal sidewall and proximal dorsum pinch easily without distorting the shape of the nose (Fig. 23-3A). If the primary wound is directly adjacent to one of these reservoirs, a single-lobed rhombic flap may be possible (Fig. 23-3B). Adding lobes for a bilobed or trilobed flap may be necessary to bridge the distance between the primary wound and the tissue reservoir (Fig. 23-3C).

Figure 23-3. (A) Tissue reservoirs on or near the nose. (B) A single-lobed rhombic flap may be used when the tissue reservoir is immediately adjacent to the primary defect. (C) Two or three lobes may be needed for more distal defects in order to bridge the distance between the primary defect and an appropriate donor site.

Tension vectors

Transposition flaps reorient and displace tension vectors to adjacent tissue reservoirs, thereby preserving the position of free margins and restoring contour at the primary defect. In general, tension is transferred from the primary defect to the terminal donor site or lobe (i.e., the secondary lobe of a bilobed flap and the tertiary lobe of a trilobed flap; Fig. 23-4). Closing the terminal donor site should allow rotation of the flap into the primary defect with minimal tension (Fig. 23-5). If tension at the primary defect is still excessive, strategically placed tacking sutures can anchor flaps to immobile

structures and minimize tension across the dermal sutures (Fig. 23-6). On the central face, tacking the undersurface of the flap to the origin of the zygomaticus major muscle, the inferior orbital rim, or the medial canthal tendon can prevent lower eyelid ectropion, and tacking sutures to the pyriform aperture can mitigate the risk of alar margin distortion. These tacking sutures also recreate contour when transposition flaps drape over concavities, such as the alar groove or nasal facial sulcus.

Figure 23-4. Transposition flaps displace tension from the primary defect to the final donor site (*stars* denote key stitch and *arrows* demonstrate direction of tension vector).

Figure 23-5. Closing the terminal donor site allows transposition of the flap into the primary defect with minimal tension. (A) Rhombic flap designed and incised. (B) The first key stitch closes the donor site. (C) After closure of the donor site, the flap drapes over the primary defect.

Figure 23-6. Secondary motion from suture placement near the inferior lateral orbital rim, where a secondary key stitch would be placed, may risk ectropion. This is mitigated by use of tacking sutures from the undersurface of the flap to the origin of the zygomaticus major, thereby suspending the flap in place and minimizing secondary motion near the vulnerable eyelid.

Pivotal restraint and flap shortening with increased angle of rotation

Visualizing a rhombic flap as a rotation flap with a large backcut helps illustrate the consequence of pivotal restraint on flap movement (Fig. 23-7). The fixed base at the pedicle tethers the flap and serves as a pivot point as the flap is rotated toward the primary defect. The pivot points for a rhombic flap are shown in Figure 23-8. As the arc of rotation increases, pivotal restraint increasingly restricts and shortens the flap length.¹ If the shortened flap does not have enough surface area to cover the defect, the consequent secondary motion of the recipient tissue will increase tension at the primary defect and may compromise the blood supply of the distal flap (Fig. 23-8). Preoperative flap design must account for pivotal restraint to avoid excessive tension, especially if secondary motion would displace a free margin.

Figure 23-7. A rhombic flap depicted as a rotation flap with a large back cut. As with a rotation flap, a rhombic flap is subject to pivotal restraint both at the base of the defect and at the terminus of the back cut.

Figure 23-8. If the flap design does not take into account the consequences of pivotal restraint and the recipient site is unable to provide secondary motion, excess tension may compromise blood supply to the distal edges of the flap.

Placement and excision of standing cones

When the flap is transposed to the primary defect, a standing cone, or dog ear, forms at the base of the pedicle. As the arc of flap rotation increases, the standing cone encroaches further into the vascular pedicle of the flap (Fig. 23-9). The standing cone is typically excised to prevent contour irregularities, though if immediate excision would narrow the pedicle and threaten the flap's blood supply, removal can be delayed.

Figure 23-9. An increased arc of rotation when transposing a flap into the primary defect results in further encroachment of the standing cone into the flap pedicle, which can compromise blood supply. The standing cone is directed away from the vascular pedicle when possible. Delayed removal can be considered if immediate removal would threaten the flap's viability.

Influences on flap vascularity

Flap vascularity is primarily influenced by three factors:

- (1) the depth of flap elevation;
- (2) the width of the flap pedicle;
- (3) the distance from flap tip to base of flap.

Depth of flap elevation

The depth of flap elevation impacts the size and perfusion pressure of the vessels within the pedicle. Deeper elevation planes incorporate vessels with larger diameters and greater perfusion pressures. The plane of flap elevation differs by anatomic location, and appropriate selection of undermining planes balances maximizing the blood supply with protection of critical anatomic structures (especially branches of the facial motor nerve). Most transposition flaps are elevated at the junction of the subdermal fat and fascia (Fig. 23-10). Routine exceptions include flaps on the midline nose and forehead, which are usually elevated deep to the muscles of facial expression, and those on the scalp, which are elevated deep to the galea aponeurotica (Fig. 23-11).

Figure 23-10. Transposition flap elevated underneath the subdermal fat, which consists of smaller, tightly packed lobules. Note that the plane of undermining is above the larger lobules of the buccal fat pad.

Figure 23-11. Transposition flaps on the nose are elevated deep to the muscular layer, above the perichondrium or periosteum.

The width of the flap pedicle

A narrow vascular pedicle compromises the blood supply to the flap. Factors influencing the pedicle width include the flap takeoff point and angle from the defect, the location of the standing cone at the pedicle base, and the number of lobes of the flap (e.g., bilobed versus trilobed). Distal takeoff

points result in a narrower pedicle than a proximal takeoff point (Fig. 23-12). The takeoff angle is the angle created between the first limb of the rhombic flap and the primary defect (Fig. 23-13A). As the takeoff angle becomes more acute, the width of the flap pedicle increases (Fig. 23-13B). However, more acute takeoff angles usually require greater secondary motion around the primary defect for wound closure. As noted above, as the arc of flap rotation increases, the standing cone encroaches further into the vascular pedicle of the flap. Finally, as the number of lobes increases, the width of the flap pedicle is enlarged, increasing flap vascularity (Fig. 23-14).

Figure 23-12. Compared to flaps with a takeoff at the midpoint of the defect (**top**), flaps with distal takeoff points result in a narrower vascular pedicle, which may compromise blood supply (**bottom**).

Figure 23-13. Closure of the donor site of a flap with an acute takeoff angle widens the defect, increasing the sharing of tension at the recipient site. Conversely, flaps that take off at a right angle to the defect require less secondary motion.

Figure 23-14. Bilobed flap design for a defect on the distal nose. The standing cone has a slight vertical orientation to avoid alar elevation. Note the narrow and tenuous vascular pedicle (*bracket*). Closure of the tertiary defect (*green arrows*) would distort the alar free margins. Converting from bilobed to trilobed flap (**B**) results in a wider, more robust vascular pedicle (*bracket*) and creates a terminal donor site that is vertically oriented to minimize alar distortion located at more favorable position within a generous tissue reservoir that facilitates side-to-side closure (*green arrows*).

The length of the flap relative to the pedicle width

The transposition flap's distal tip is most vulnerable to ischemia, and all long flaps with narrow pedicles are vulnerable to ischemic compromise.

Transposition flaps are often purposefully drawn with a long distal tip and apical angle of 30 degrees or less to ease closure and minimize standing cone formation at the terminal donor site (banner flap design). Consequently, the flap is frequently longer than necessary to cover the defect. Either the defect can be extended and angulated to accommodate the triangular tip, or the distal flap can be trimmed to match the rounded defect. Trimming the angulated distal flap to fit the rounded defect reduces the risk of ischemia and is generally preferable.

Tension on the flap

High tension on the flap increases the risk for ischemia. Common causes of tension include a flap with less surface area than the defect and transposition of the flap to a recipient bed with tight immobile skin. Transposition flaps on the scalp are particularly vulnerable to excessive tension.

Altering the defect or the flap to optimize flap design and execution

In order to maintain the appropriate contour of the recipient site, the primary defect is often deepened to match the flap thickness. For example, a shallow defect on the nasal tip may be deepened to perichondrium to match the thickness of a bilobed flap, which is elevated in the perichondrial plane.

Additionally, the defect may be altered or enlarged to place scar lines along cosmetic subunit junctions. For instance, on the nasal ala, the defect may be extended to the alar rim to camouflage the horizontal scar line from a nasolabial transposition flap. Similarly, a defect on the lip may be extended to the vermilion-cutaneous junction (Fig. 23-15).

Figure 23-15. A defect on the upper lip is extended to the vermilion–cutaneous junction in order to camouflage the incision within the cosmetic subunit junction. Preoperative view and design (A), appearance immediately after closure (B) and appearance prior to revision to recreate the melolabial fold (C).

CONSIDERATIONS FOR SPECIFIC TRANSPOSITION FLAPS

Single-lobed (rhombic, nasolabial, or banner) transposition flaps

The donor site of single-lobed transposition flaps is immediately adjacent to the defect. This proximity magnifies the impact of donor site selection and flap design on the ease of wound closure, flap vascularity, and the degree of secondary motion required to close the defect.

Surface area of the flap versus the primary defect

The appropriate donor site for a single-lobed flap should have adequate tissue laxity to close the secondary defect after elevating a flap with sufficient surface area to cover the primary defect. Pinching the skin adjacent to the wound gauges tissue laxity. If the surface area of the flap and primary defect are similar, secondary motion at the primary defect will be minimized. If tension at the donor site requires an undersized flap, secondary motion will

be necessary to close the difference between the flap and the primary defect, potentially displacing adjacent free margins (Fig. 23-16).

Figure 23-16. Minimal secondary motion at the recipient site is required when the flap area is equal to the defect area. An undersized flap increases the degree of secondary motion at the primary defect. In critical anatomic areas, secondary motion at the recipient site increases the risk of free-margin distortion. A rhombic flap with a surface area equal to that of the defect is designed (A). Two-month follow-up shows excellent eyelid position (B).

The impact of takeoff point and angle on blood supply and tissue biomechanics

After a suitable tissue reservoir is identified, one must determine both the takeoff point and angle. The takeoff point can influence flap vascularity and length. The takeoff point is usually at the midpoint of the defect (Fig. 23-17A). For ovoid or asymmetric defects, the takeoff point most often originates from the short axis. Taking off from the long axis of an asymmetric defect requires a greater arc of rotation and flap length, which both threaten the flap's blood supply. Distal takeoff points narrow the pedicle and compromise the blood supply (Fig. 23-17B). Occasionally, positioning the takeoff point closer to the base of the defect may be advantageous, as this increases the width of the vascular pedicle and may move the takeoff point (and the first key suture that bears maximal tension) away from critical

anatomic structures. The trade-off is that a longer, more vulnerable flap is necessary to reach the defect (Fig. 23-17C).

Figure 23-17. The flap takeoff point and angle of a rhombic flap impacts blood supply and tissue biomechanics. The takeoff point is usually at the midpoint of the defect, originating from the short axis for an asymmetric defect. (A) Distal takeoff point creates a narrow pedicle. (B) Proximal takeoff point results in a longer flap to cover the defect that may be vulnerable to ischemia.

The takeoff angle between the first limb of the rhombic flap and the primary defect also affects blood supply and flap biomechanics. To illustrate this principle, consider a traditional rhombic flap compared to the

Dufourmental modification. The traditional takeoff angle for the classic rhombic flap is perpendicular to the defect, resulting in a flap that moves 90 degrees into place. Due to the nearly perpendicular tension vectors of the first and second key stitches, there is minimal secondary motion at the primary defect (Fig. 23-18). Avoiding secondary motion is a priority for primary defect near free margins or with immobile surrounding skin. As the takeoff angle becomes more acute, the width of the flap pedicle increases. However, more acute takeoff angles usually require greater secondary motion around the primary defect, because the tension vectors to close the primary and secondary defects compete. The Dufourmental modification takes off at a more acute angle and decreases the flap's arc of rotation of the flap.² Closing the donor site of a flap with an acute takeoff angle widens the primary defect and requires secondary motion for closure around the relatively undersized flap (Fig. 23-19).

A

B

Figure 23-18. The takeoff angle between the first limb of the rhombic flap and primary defect is usually 90 degrees. There is no sharing of tension since the primary key stitch and secondary key stitch are nearly perpendicular. Acute takeoff angles result in competing tension vectors caused by closure of the primary and secondary defects. As a result, greater secondary motion is required at the primary defect.

Figure 23-19. Modified takeoff angle for a rhombic flap used to repair a defect on the proximal nose. (A) Flap design with an acute takeoff angle. (B) Immediate postoperative appearance. Note the secondary motion at the primary defect. (C) Six-month follow-up.

Banner flaps rely on a takeoff angle that is nearly tangential to the defect (close to 180 degrees); coupled with the removal of a standing cone at the opposite angle and the elevation of a long narrow flap pedicle (the banner), such flaps permit transposition of significant portions of tissue over large arcs.

Specific examples of single-lobed transposition flaps

Nasolabial transposition flap. The nasolabial single-lobed transposition flap is useful to reconstruct defects of the alar groove and ala, and is one of the most frequently performed banner flaps.³ The flap recruits tissue from the

generous reservoir at the nasolabial fold. Since the alar groove and ala have scant fat, and since the skin adheres firmly to the dermal insertions of the underlying muscles, this flap can appear too thick and pincushion without a precise undermining plane and tacking sutures to recreate the alar groove.

The key design characteristics of the nasolabial transposition flap are shown in (Fig. 23-20). The medial arm of the flap takes from the lateral aspect of the nasal defect and extends inferiorly along the nasolabial fold. The lateral arm of the defect extends along the cheek in a parallel line that gently tapers to join the inferior nasolabial fold with 30 degrees or less. The horizontal widths of the proximal flap and defect should be identical. The superior aspect of the cheek limb of the flap should remain a couple of millimeters inferior to the origination point of the medial limb. This slight discrepancy is important to orient the primary tension vector in a superomedial vector that recruits skin from the mobile buccal cheek.

Figure 23-20. Design characteristics of the nasolabial transposition flap include equal widths of the flap and defect, maintaining the width of the flap until past the defect, and tapering the flap arms to an angle of 30 degrees or less.

The flap is elevated to include only the subdermal fat ([Fig. 23-21A](#)). If it includes the nasolabial fat pad, the flap will have too much volume. The nasolabial fold and cheek are undermined in the same tissue plane.

Figure 23-21. (A) Nasolabial transposition flap elevated under the subdermal fat and dissected off the lip elevators. Flaps that include the nasolabial fat pad will appear bulky. (B) Tacking the cheek to the pyriform aperture recreates the nasofacial sulcus and prevents distortion of the ala and tip. A slight dimple is desirable. (C,D) Tacking the base of the flap to the caudal margin of the transverse nasalis recreates the alar groove. A dimple is again desirable. (E) Desired contours should be evident immediately postoperatively.

The key suture closes the donor defect at the flap's origination point. If the wound is under high tension, tacking the cheek to the origin of the transverse nasalis along the pyriform aperture may be necessary to avoid lateral distraction of the nose ([Fig. 23-21B](#)). The distal portion of the flap is trimmed to match the size of the defect, and it is sutured to the primary defect. The alar groove has a deep concavity and the flap will pincushion if the dead space is not closed. Tacking the base of the flap to the caudal margin of the

transverse nasalis muscle is usually necessary to close dead space and restore contour of the concave alar groove (Fig. 23-21C). Transposition of the flap creates a standing cone along the nasal sidewall, which is removed while taking care to preserve the flap pedicle. Pincushion deformity of the transposed portion of the flap is the most common complication, which can be minimized by wide undermining of the recipient site in the perichondrial/periosteal plane, placement of tacking sutures on the flap to the base of defect, and judicious thinning of the flap resulting in a concave surface when the flap is inset. The desired contour should be present immediately postoperatively (Fig. 23-21D).

Double rhombic flaps. Two rhombic flaps may be used to cover defects that are too large for a single flap. Different variations of this strategy have been described. One variant has opposing rhombic flaps from the opposite sides of the primary defect (Fig. 23-22).^{4,5} Another variant has two mirror image flaps on each side of the primary defect.^{6,7} Each flap has a Dufourmentel modification with an acute takeoff angle, and they share a standing cone deformity when they are transposed.

Figure 23-22 . Mohs defect on the temple repaired with opposing rhombic flaps. (A) Flap design. (B) Flaps sutured into place. (C) Three-month follow-up.

Multilobed (bilobed, trilobed, etc.) transposition flaps

When there is not enough issue immediately adjacent to the wound to allow closure with a single-lobed flap, additional lobes may be added to access a suitable tissue reservoir. A classic example is the use of bilobed and trilobed flaps to close distal nasal defects. The additional lobes access the more freely mobile tissue on the superior third of the nose, displacing tension away from the vulnerable free margin of the nose. Multilobed flaps are typically chosen when the surgeon needs to (1) recruit tissue from a more sizable reservoir than is available immediately adjacent to the defect, (2) reorient the tension vector of the key stitch or displace it to a more distant location, or (3) increase the width of the pedicle in order to minimize the risk of vascular compromise. For a full discussion of bilobed flaps, see [Chapter 24](#).

Specific examples of multilobed transposition flaps

Bilobed flap. If a rhombic flap is not possible because tension on the skin immediately adjacent to the primary defect is excessive or causes anatomic distortion, the bilobed flap can reach donor sites more remote from the defect. Compared to the rhombic flap, the geometry and execution of the bilobed flap are more complex. Excellent reviews have been written on this topic.^{8–11} The bilobed flap is most commonly utilized to repair wounds on the nose or near the eyelid, though it can be used in nearly any anatomic location ([Figs. 23-23 and 23-24](#)).¹²

Figure 23-23. Defect on the radial dorsal hand repaired with a bilobed flap. (A) Mohs defect. (B) Flap design. Note the more favorable location of the tertiary defect which facilitates closure. (C) Immediate postop appearance. (D) Long-term follow-up.

Figure 23-24. Defect on the right infraorbital cheek repaired with a laterally based bilobed flap. (A) Mohs defect and flap design. (B) Immediate postop appearance. (C) Long-term follow-up (14 months, treated with pulsed-dye laser).

Like the rhombic flap, the bilobed flap also rotates approximately 90 degrees. However, the bilobed flap distributes the rotation between the two lobes, each rotating 45 degrees. The second lobe incorporates a Z-plasty that helps to push the flap toward the primary defect (Fig. 23-25). If the primary defect is near a free margin, the tension vector to close the donor site for the secondary lobe (i.e., the tertiary defect) should generally be parallel to the free margin to preserve its position. To avoid secondary motion at a primary defect near a free margin, the primary lobe should also be sized to match the primary defect. The secondary lobe may have 85% to 90% of the surface area of the primary defect. The design details of a nasal tip defect repaired with a bilobed flap are shown in (Fig. 23-26).

Figure 23-25. The bilobed flap represented as two consecutive Z-plasties that lengthen the flap.

Figure 23-26 . Key design principles of a bilobed flap on the nose. (A) The diameter of the primary lobe is approximately equal to the diameter of the defect. The secondary lobe has a diameter 80% to 85% of the primary lobe and is not tapered too quickly. The standing cone is 30 degrees at the apex and oriented as vertically as possible without compromising the vascular pedicle. (B) Appropriately sized lobes minimize secondary motion at the nasal tip (*red arrow*). The final donor site is oriented such that the primary tension vector of its closure is parallel to the free margin (*green arrows*). (C) Immediate postoperative appearance. Note the absence of free-margin distortion. (D) Appearance at 8 months postoperatively after treatment with pulsed-dye laser.

The first key suture closes the tertiary defect and ideally pushes the flap toward the primary defect. The second key suture sets the primary lobe into

the defect. The exact position of this suture may vary or require adjustment to create tension vectors that avoid anatomic distortion, to align the standing cone, and to adjust the sizing of the primary lobe. The secondary lobe usually has excess length and must be trimmed to match the secondary defect.

Trilobed flap. The trilobed flap has tissue mechanics similar to the bilobed flap with a few distinct advantages (Fig. 23-27). First, its third lobe allows the flap to reach tissue reservoirs increasingly remote from the primary defect, and it is particularly useful to reconstruct distal nasal defects. Second, the third lobe extends the arc of rotation to 120 to 150 degrees and may provide a more favorable tension vector to close the quaternary defect. Third, the additional lobe adds the benefit of another Z-plasty, which decreases the tension to transpose the flap, an important advantage when even mild tension at the distal nose can distort the free margins. Finally, the third lobe increases the width of the flap pedicle. If the orientation of the standing cone would cut into the pedicle of a bilobed flap, the increased pedicle size of a trilobed flap can improve blood supply.¹³

A

B

C

Figure 23-27. The trilobed flap has several design advantages. (A) The flap rotates 120 to 150 degrees, places the final defect in a more favorable location such that the key tension suture preserves the position of alar margins, and allows for a wide, more robust vascular pedicle. The trilobed flap also gains an additional Z-plasty advantage. (B) Immediate postoperative appearance. Note the preservation of alar symmetry. (C) Six-month follow-up.

SPECIAL CIRCUMSTANCES FOR TRANSPOSITION FLAPS

1. *Delaying removal of the standing cone*

If immediate removal of the standing cone would compromise blood supply, its excision may be delayed until the flap has integrated into the recipient site (usually around 3 to 4 weeks). The need to delay standing cone removal is most likely for flaps whose large arc of rotation forms a standing cone that encroaches on the vascular pedicle (Fig. 23-28).

(C) Immediate postoperative appearance. The standing cone was left in place, resulting in a contour deformity. (D) Appearance after staged excision of standing cone.

2. Combining transposition flaps with other reconstructions

Large surgical defects may require a combination of a transposition flap and another flap or graft. The additional reconstruction may be necessary to help cover the primary defect or the secondary defect after transposing the flap (Fig. 23-29).

Figure 23-29. Multisubunit defect (cheek and ear) repaired with a rhombic flap and full-thickness skin graft. (A) Mohs defect. (B) Rhombic flap design to cover cheek subunit. (C) Rhombic flap sewn into place. (D) A Burow's graft was used to cover the ear subunit. (E) Immediate postoperative appearance. (F) Six-month follow-up.

COMPLICATIONS

Pincushioning, or trapdoor deformity, may occur with transposition flaps, especially on the nose. Several etiologies have been suggested, such as excessive flap thickness, inadequate undermining, and circumferential wound contraction. Strategies to minimize pincushioning include appropriately sizing the flaps, careful suturing of all anatomic layers, and closing any dead space under the flap. Contact inhibition of the pincushioning effect may be accomplished by assuring that the undersurface of the flap is sutured to the defect; a flap that is kept in contact with the wound bed may have a decreased tendency to pincushion. These buried quilting or basting sutures do not need to be tacked to deeper immobile structures, as is performed with suspension sutures, since the goal is to maintain the contact of the flap base with the underlying defect, not to recreate a natural sulcus. The vascular supply to the flap should never be compromised, however, by overly zealous attempts at contact inhibition. If intralesional corticosteroids do not resolve pincushioning, surgical thinning may be necessary.

The curved lines that result from most transposition flaps require meticulous suturing, as they rarely fall along cosmetic subunit junctions or relaxed skin tension lines. This attention to detail is particularly critical for successful execution of flaps on sebaceous skin, such as the distal nose.

Transposition flaps that span multiple facial subunits may ablate cosmetic subunit junction lines. Patients may be prepared for the possibility of staged reconstruction to restore a concave subunit junction, such as the alar groove or melolabial fold ([Fig. 23-30](#)).

Figure 23-30. Transposition flaps that span multiple subunits may ablate cosmetic subunit junction lines. Perioral Mohs defect (A) repaired with an inferiorly based rhombic flap (B). The primary lobe of the flap interrupts the melolabial fold and is apparent immediately postoperatively (C). Appearance prior to revision (D). After staged reconstruction to recreate the melolabial fold (E).

When recruiting tissue from distant sites, transposition flaps may not match the contour, texture, and hair density of the defect. For example, when recruiting from an area with substantial fat, such as the cheek, to cover an area with minimal subdermal fat, such as the lip, a bulky flap is expected (Fig. 23-31). Surgeons may counsel patients when additional procedures, such as staged surgery or hair removal, are anticipated (Fig. 23-32).

A

B

C

Figure 23-31. Staged reconstruction may be anticipated when recruiting from distant sites. Upper lip Mohs defect (A) repaired with a bilobed flap which recruits skin from the cheek. (B) Immediate postoperative appearance. Note the ablation of the melolabial fold and bulkiness of the primary lobe,

which contains substantial fat. (C) Prior to revision. (D) Appearance after staged reconstruction to recreate the melolabial fold and debulk the primary lobe.

Figure 23-32. When recruiting tissue from donor sites with a different hair density than the defect, patients may be counseled regarding the need for hair removal procedures (such as shaving or laser hair removal) at the recipient site. (A) Mohs defect on the right lower eyelid and infraorbital cheek. (B) Trilobed flap design containing terminal hairs. (C) Immediate postoperative appearance. Note the transposition of the dense terminal hairs that are even more apparent at the 1-week follow-up (D).

CONCLUSIONS

Transposition flaps enable displacement of tension to a more favorable location and recruitment of tissue from adjacent and distant tissue reservoirs. They can be used to repair defects in nearly any area of body, especially in locations where preserving the position of free margins and restoring contour at the primary defect are of paramount importance.

CHAPTER 24 Bilobed Flaps

Joy Kunishige
John A. Zitelli

SUMMARY

- Over the past two decades, the bilobed flap has become a workhorse technique for nasal reconstruction.
- While often conceptualized as a transposition flap, it has a significant rotational component and also incorporates a Z-plasty, making it a powerful technique for nasal reconstruction and beyond.

Beginner Pearls

- To minimize the risk of distortion, the width of the secondary lobe, primary lobe, and primary defect are all designed to be of equal size, though some authors have suggested adopting undersized primary and secondary lobes.
- Laxity of the medial cheek and nasofacial sulcus skin is recruited when closing the tertiary defect, permitting a tension-free closure.

Expert Pearls

- A prototypical bilobed flap on the nose involves several unique features:
 - Greater movement about the pivot point because of its position near the recruitable medial cheek
 - Double transposition design displacing the tension vector away from the primary defect
 - Lengthening effect of the Z-plasty to overcome pivotal restraint
 - Less than 45 degrees of transfer between each lobe to minimize standing cone deformity.

Don't Forget!

- Always orient the tertiary defect vertically, as any diagonal vector may cause elevation of one of the alar rims.
- The flap can be drawn freehand by imagining two hearts overlapping, which inherently creates lobes of equal width and length.
- Meticulous suturing technique is a must for minimizing the appearance of curvilinear scars.

Pitfalls and Cautions

- Extranasal bilobed flaps may have more of a tendency to pincushion than those on the nose.
- Deepen the defect on the nose to the cartilage, making room for the incoming flap. This will prevent additional bulk adding to the temporary trapdooring or edema.

Patient Education Points

- As with all flaps, warn patients that the length of the suture lines will be significantly longer than the defect.
- Always advise patients that they may have a multi-stage procedure, and that trapdooring is likely to occur. Patients will be much more understanding regarding the need for intralesional steroid injection or other intervention if they were prewarned that this may occur.

Billing Pearls

- Flap repair codes (140XX series) include the excision component, so it is not appropriate to bill both an excision and a flap repair code simultaneously.
- Mohs codes may be submitted along with flap repair codes, though they may be subject to the multiple- procedure reduction rule.
- When coding a flap, medical necessity is the ultimate arbiter of appropriateness.

CHAPTER 24 Bilobed Flaps

INTRODUCTION

Over the past two decades, the bilobed flap has become a workhorse technique for nasal reconstruction. While often conceptualized as a transposition flap, it has a significant rotational component and also incorporates a Z-plasty, making it a powerful technique for nasal reconstruction and beyond.

HISTORY AND EVOLUTION OF THE BILOBED FLAP

Although classified as a double transposition flap, the bilobed flap was actually described *before* the classic single transposition rhombic flaps of Limberg¹ and Defourmentel.² The original design is attributed to Esser, who published its use in 1918 for nasal tip defects (Fig. 24-1).³

Figure 24-1. Original Esser design.

According to Esser's initial design, the angle of tissue transfer between each lobe of the flap was 90 degrees.³ The total transposition thus took place over 180 degrees, as it relied on the nasal dorsum tissue to cover defects on the nasal tip. This large degree of rotation forced the lobes to be relatively wide, resulting in an obvious standing cone deformity around the pivot point. Thus, this flap technique, published in German, went largely unnoticed for at least three decades.

In 1953, Zimany revisited the flap and expanded its application to defects on the trunk and soles.⁴ In 1981, McGregor and Soutar noted that the angle of tissue transfer could be varied from the original 90 degrees for each lobe.⁵ Indeed, in their study, the average angle of transfer was only 108 degrees. They also highlighted both the rotational and transpositional components of the flap.

In 1989, Zitelli published three modifications that would make the bilobed flap among the most commonly used flaps for defects on the lower nose.⁶ The first improvement was formally narrowing the angle of transfer to a maximum of 45 degrees between each lobe. This decreased the total angle of transfer to no more than 90 to 110 degrees. The second modification was to insert a Burow's triangle between the primary defect and the pivot point. Intentional design and removal of standing cones upfront were personal preferences of

Zitelli. These two changes eradicated prominent tissue protrusion around the pivot point. Finally, he advocated wide undermining of the flap and surrounding tissue to reduce pincushioning. Shortly thereafter, Burget confirmed excellent results using these design modifications on the nose.⁷

PRINCIPLES OF THE BILOBED FLAP

Advantages of the bilobed flap

The nose presents several reconstructive challenges. The topography is complex with multiple convex and concave surfaces that must be maintained. The alar rims are mobile free margins, and are easily displaced. The skin over the lower third of the nose also has limited mobility, and generally cannot be recruited for more than the narrowest primary closures or advancement flaps. Finally, retaining the function of the nose and nasal valves is paramount.

The bilobed flap is thus particularly suited for reconstruction on the distal nose, as it enables the surgical site to be filled with nearby skin of similar color and texture, while concomitantly leaving the free margin and airway remains undisturbed, as all tissue movement and tension are concentrated on closing the tertiary defect on the nasal dorsum.

Design principles

To minimize the risk of distortion, the width of the secondary lobe, primary lobe, and primary defect are all designed to be of equal size (Fig. 24-2). To facilitate closure, the secondary lobe may be slightly narrower when it is located on relatively immobile skin adjacent to the medial canthus. Some authors have suggested adopting undersized primary and secondary lobes.⁸ This approach can be considered if there is considerable tissue laxity around the primary defect.

Figure 24-2. Zitelli modifications of the bilobed flap. Decreased angle of tissue transfer and incorporation of a Burow's triangle reduces standing cone deformity. The apex serves as a focal point for the design. Each donor lobe is designed around one arc through the center of the defect, and another arc through the distal end of the defect.

If the flap is meticulously designed so that the lobes of the flap equal the width of the defect, then virtually all of the flap's tension is in closing the tertiary defect. This is analogous to a standard transposition flap closure, where the key suture—and attendant tension—is in closing the secondary defect. As such, the bilobed flap's tertiary defect should be oriented vertically. Any diagonal vector to this final defect may cause elevation of one of the alar rims.⁹

The ideal defect for the bilobed flap is small (less than 1.5 cm) and located on the lateral nasal tip or distal nasal sidewall. When performed in this location, the skin laxity of the medial cheek and nasofacial sulcus is recruited when closing the tertiary defect. In theory, however, defects of any size and in any nasal location may be repaired with a bilobed flap, as long as

the flap can be drawn entirely on the nose with the final lobe pointing superiorly. The upper limit of a defect amenable to this procedure is contingent on the size of the patient's nose, the location of the defect on the nose, and the elasticity of the nasal bridge skin. Limitations of the bilobed flap—or, at least, a realization that there is less room for error—become evident when defects are larger or arise within rigid sebaceous skin.¹⁰

Biomechanics

At the first glance, the bilobed flap appears to be a modified rotation flap with some component of transposition. However, during the movement of tissue, there is a greater release of tension than would be expected with rotation alone. The mechanical release of tension is due to the Z-plasty that is inherent within the flap's design.^{11,12} The lengthening effect of the Z-plasty overcomes the otherwise significant pivotal restraint, enabling the primary defect to be repaired without tension.

A prototypical bilobed flap on the nose involves several unique features: greater movement about the pivot point because of its position near recruitable medial cheek, double transposition design displacing the tension vector away from the primary defect, lengthening effect of the Z-plasty to overcome pivotal restraint, and less than 45 degrees of transfer between each lobe to minimize standing cone deformity.

The bilobed flap: step-by-step

Basic steps for execution of the standard bilobed flap for the repair of a defect on the distal third of the nose are outlined here. Ideal angles have been calculated for a perfect design of the flap.^{13,14} However, the flap can be drawn freehand by imagining two hearts overlapping, which inherently creates lobes of equal width and length (Fig. 24-3).

Figure 24-3. Series of photos for standard bilobed flap on the distal nose. (A) Basal cell carcinoma. (B) Postexcision using Mohs technique. (C) Bilobed flap design. (D) Immediately postrepair with bilobed flap. (E) Three months postoperative. (F) Six months postoperative. Note the mild pincushioning present at the 3-month follow-up that resolved spontaneously. Dermabrasion or scar revision was not utilized.

Step One. Design and draw the bilobed flap. First, draw a long and narrow Burow's triangle from the surgical defect to the apex of the flap. If possible, the superior edge of the Burow's triangle is parallel to the alar crease. The apex should be positioned just above the alar crease, so any residual standing cone does not raise this concavity. The apex serves as a

focal point for the rest of the design. Each donor lobe is designed around one arc through the center of the defect and another arc through the distal end of the defect. Each lobe's radius is positioned approximately 45 degrees from the other, and 45 degrees from the defect.

Step Two. Excise the Burow's triangle. Debevel and remove any remaining subcutaneous tissue from the primary defect. Deepening the defect is preferable to thinning the flap. Adipose can safely be trimmed beneath the pivot point to prevent tissue redundancy.

Step Three. Incise and lift the flap. Undermine widely beneath the flap and surrounding tissue in the submuscular plane, just above the perichondrium or periosteum. Undermine the fibrous tethers along the lateral sidewall, at the junction of the nasal bone and the upper lateral cartilage. This releases the skin and allows recruitment of loose medial cheek skin. Thin the distal-most edge of the primary lobe so that it does not add bulk to the alar rim. The flap thickness should be slightly thinner than the depth of the defect.

Step Four. Precise hemostasis. Avoid electrodesiccation of the lobule tips, the areas most at risk for necrosis. Electrodesiccation of the epidermis and dermis is not necessary.

Step Five. The first stitch or "key stitch" closes the tertiary defect. Closure of the tertiary defect should be exactly horizontal, or unwanted displacement of the alar rims and medial canthi may ensue. After closing the tertiary defect, the flap should easily drape into place without tension. If a gap is visible, it is due to the primary wound gaping, and resolves when the tissue is brought back to its baseline position. The next suture usually connects the inferior distal edge of the primary lobe to the primary defect near the medial alar rim. Alar rim position is assessed before suturing the remainder of the flap.

Step Six. Trim the secondary lobe to fit the secondary defect, and close the remaining wound edges in a layered fashion. Meticulous buried vertical mattress stitches are essential to create an epidermal seal and reduce visible lines. Ensure that all layers of the wound edges are approximated, and carefully pull together any dermis or muscle that may have retracted away from the wound edge.

Step Seven. Bandage the wound in a standard fashion with a 24-hour pressure bandage. Counsel the patient to expect mild edema of the distal

portion of the flap in around 1 to 2 months; this should resolve with massage and time. If pitting along the surgical line develops, the patient may return in 2 months or later for dermabrasion.

MODIFICATIONS OF THE BILOBED FLAP

Trilobed flap

The most common variation on the bilobed flap is the trilobed flap. When faced with a defect where there is little tolerance for tension on the surrounding skin, a bilobed should be considered; when a bilobed design presents challenges, consider the trilobed flap (Fig. 24-4).¹⁵

Figure 24-4. Series of photos for trilobe flap on infratip. Mohs defect (A), immediately postrepair (B), and 3 months postoperative (C).

A trilobed flap may be a viable option for distal nasal defects, such as those on the infratip. Beginning at the defect, draw similarly sized lobes until the final lobe is pointing exactly vertically. Though the additional lobe will

cause the total angle of flap transfer to increase, each lobe is only rotating 45 degrees or less. Therefore, a trilobed flap does not cause any additional standing cone deformity around the pivot point.

A trilobed flap with a diminutive vertical Burow's triangle has been reported for defects on the medial ala; however, a very short Burow's triangle with its apex in the alar crease could theoretically lead to nasal valve constriction.¹⁶ A quadrilobed flap has also been described, again for distal tip defects.¹⁷ In these cases, however, a medially based bilobed flap (as discussed below) may be a more straightforward option.

Medially based bilobed flap

When the defect appears too big for a bilobed flap, consider drawing the flap with the Burow's triangle oriented medially, rather than laterally (Fig. 24-5).¹⁸ A contralateral or medially based bilobed flap is an easy solution for a large and deep defect, and for select small distal alar defects.¹⁹ Although the vascular supply is not as rich in these locations, due to an increased distance from the angular artery, medially based bilobed flaps are reliable. Importantly, design the flap with sufficient lobe length to accommodate draping over the convex midline. As with all large bilobed flaps, assure that there is adequate laxity on the upper two-thirds of the nose to permit closure of the tertiary defect.

Figure 24-5. Series of photos for medially based bilobed flap. Mohs defect too large for standard bilobed flap (A), immediately postrepair (B,C), and 3 months postoperative (D,E),

Figure 24-5. and 6 months postoperative (F–H).

Bilobed flap for two defects

The bilobed flap can also be used to repair two nearby defects, especially when the flap is designed so that the second defect lays in the area representing the nascent Burow's triangle.²⁰ The design of the Burow's triangle can thus be elongated to provide coverage for a smaller defect inferolateral to the first.

Lengthening the primary lobe

Lengthening of the primary lobe of the flap to overcome pivotal restraint has been described as a strategy to better reach the distal edge of the primary defect and overcome pivotal restraint.²¹ The defects described in this report, however, were not the typical size or in the usual location for a bilobed flap.

When the bilobed flap is used to repair a defect on the nasal tip, the flap will naturally recruit skin from the medial cheek and nasofacial sulcus, obviating the need for an oversized primary lobe. Still in cases where the flap is large, so that closure of the tertiary defect causes tension near the medial canthus, a longer primary lobe may be useful.

Another strategy to mitigate the challenges of pivotal restraint is to design a long and narrow Burow's triangle, approximately 1.5 times the diameter of the defect. If the Burow's triangle is significantly shorter, as can occur by necessity with larger defects, pivotal restraint may present a greater challenge.²²

Hinge flap and supporting framework

The relatively thick bilobed flap, with its underlying muscle and relatively firm skin, coupled with little to no tension on the primary defect, enables most closures to be performed without the use of cartilage grafts. For full-thickness through-and-through defects, epidermis from the Burow's triangle can be hinged over on a muscular pedicle to restore missing mucosa.

Alternatively, the epidermis and dermis can be excised, leaving muscle to be flipped in to fill a deeper defect. Cartilage struts can also be used to restore structure or support the alar rim, especially at the soft triangle that can be prone to notching. Following these deeper approaches, a standard bilobed flap can be executed for cutaneous cover.

SPECIAL LOCATIONS AND APPLICATIONS OF THE BILOBED FLAP

Chin

The key advantage of all transposition flaps is reorientation of the tension vector. In a bilobed flap, the tension vector is not only reoriented, but also distant to the defect. This enables closure of the primary defect without any tension, making it a reliable solution for defects near any free margin. As such, the bilobed flap can be used on the chin without fear of displacing the lower lip or commissure, with the added benefit of bringing in matching skin with terminal hair. Undermining is performed within the mid-adipose plane, with special care taken along the mandible where the marginal mandibular nerve is located. After completion, the straight line from closure of the tertiary defect should lie along a relaxed skin tension line, such as the marionette fold. The point of the final lobe is tucked beneath the chin to avoid a standing cone deformity at the mandible that would unilaterally accentuate the jowl (Fig. 24-6).

Figure 24-6. Series of photos for bilobed flap on chin. Mohs defect (A), immediately postrepair (B), and 6 months postoperative (C).

Lateral nasal bridge

Usually a rhombic flap will suffice here. However, a bilobed flap can also be used, with closure of the tertiary defect camouflaged within a glabellar fold.

Periorbital region

Again, the bilobed flap can be used without fear of pulling on the lid margin or lateral canthus. A superiorly based design has been reported to guarantee no downward pull on the lower lid.^{23,24}

Large or horizontally oriented cheek defects

On the cheek, the bilobed flap is useful when rotation flaps will not provide enough tissue coverage (Fig. 24-7). This occurs when the defect is large and located on the mid-cheek, away from the central face. In this location, the amount of remaining cheek skin available may be insufficient to fill a large cheek defect.²⁵ Additionally, a hinge-over of subcutaneous tissue from the Burow's triangle can be used to fill a very deep defect, and a suspension suture can be used to anchor the flap to the zygoma, if needed. Similarly, horizontally oriented defects on the cheek may be closed with a bilobed or trilobed flap that may confer the added advantage that they will be smaller than a rotation flap for a similarly sized defect.

B

C

D

E

Figure 24-7. Series of photos for a bilobed flap on cheek. Large melanoma in situ (A), defect with insufficient lateral cheek reservoir for rotation flap (B), immediately postrepair (C), 3 months postoperative (D), and 1 year postoperative (E).

Helical rim

The bilobed flap has limited utility on the ear as there is a dearth of mobile skin available for recruitment. The flap may be utilized for select helical rim defects, particularly when the final lobe can be drawn to recruit skin from the postauricular sulcus. While acceptable results have been published, free grafts, helical rim advancement flaps, or pedicle flaps may be more useful in this location.

Other locations

Other published locations for reconstruction with the bilobed flap include small alar rim defects,²⁶ full-thickness alar defects,^{27,28} upper lip,²⁹ axilla, digits, perineum, extremities, and feet.³⁰

FINESSING THE BILOBED FLAP

Initial design

The key to success of any flap is precise design. The lobes should be equal in width to that of the defect. Deviation from this will induce movement in the skin and subcutaneous tissue surrounding the primary defect. On the nose, lobes should be drawn until the final lobe is directed completely vertically. Off the nose, closure of the tertiary defect should be along relaxed skin tension lines. In all locations, closure of the tertiary defect should utilize existing laxity, and not cause distortion of surrounding tissue.

Importantly, bilobed flaps on extranasal locations do not include muscle; therefore, by definition, they have a less robust vascular supply than seen on the nose. Though Cook has recommended an inferiorly based pedicle to facilitate drainage and decrease pincushioning,³⁰ the location typically dictates the orientation of the flap: the flap should be designed so that closure of the tertiary defect results in a line along relaxed skin tension lines. [Table](#)

24-1 is a summary of common pitfalls and remedies regarding the use of bilobed flaps.

Table 24-1. Common Pitfalls and Remedies

Problem	Considerations
Distorted alar rims, alar asymmetry	Be sure the secondary lobe is oriented exactly vertically, and all stitches closing this tertiary defect are horizontal, so that there is no upward pull of either ala. Also, design the primary lobe to be the exact width and length of the primary defect to eliminate movement around the primary defect.
Ipsilateral alar rim depression	Anticipate this bulldozing effect with thick sebaceous skin or when employing large angles of transposition. Slightly trim the primary lobe of the flap to compensate.
Tip necrosis	Careful pinpoint hemostasis especially near lobule tips. Do not electrodesiccate the epidermis or dermis. If tip necrosis does occur, this is usually superficial and occlusive dressings will allow the necrotic area to fill in.
Trapdooring of distal-most portion of flap	Undermine both the flap and defect widely. Remove any remaining subcutaneous tissue from the defect. Avoid “stuffing” the flap into the defect. Intralesional triamcinolone postoperatively may be helpful.
Webbing of medial canthus	Undersize the final lobe of the flap if needed. Closure of the final lobe on the nasal bridge should be with stitches that are exactly horizontal. Do not pull diagonally on any tissue, particularly near the medial canthi.
Primary lobe of flap does not reach or adequately cover the primary defect	If large flap or crossing convexity, consider measuring with a suture or adding an additional 1 mm of length to flap design. Undermine fibrous attachments at nasofacial sulcus to release more tension.
Bilobed flap does not fit on the nose	Consider a medially based bilobed. Avoid a bilobed or trilobed flap with pivot point on the nasofacial junction or crease.
Secondary lobe does not point perfectly vertical	Either draw a tertiary lobe so that the final lobe is pointing exactly vertically, or move the apex inferiorly to “tilt” the bilobed flap.
Standing cone at pivot point	Make Burow’s triangle longer so that angle of transposition between each lobe is 45 degrees or less. Also, debulk fat from beneath the pivot point.

Flap execution

First, deepen the defect on the nose to the cartilage, making room for the incoming flap. This will prevent bulk adding to the anticipated temporary trapdooring or edema. The fat directly beneath the pivot point can safely be debulked to further prevent a standing cone deformity.

Detaching the fibrous attachments of the skin from the bony structure of the nose will allow the flap to mobilize and reach as predicted. There are prominent attachments on the mid-nasal sidewall over the attachment of the nasal bone to the upper lateral cartilage. When the flap is undermined at the level of the periosteum, the fibrous bands are released, and skin can be recruited from the medial cheeks to reduce tension on the closure. These fibrous attachments can be released on both sides of the nose.

One disadvantage of this flap is the use of multiple small curved lines that do not follow preexisting skin folds or wrinkles. In theory, one could design a double rhombic flap about a single pivot point with angular lines, or modify each lobe to have pointed tips.¹³ Both of these designs still require the use of multiple short lines in various directions. Fortunately, sutured lines

can be barely noticeable if precise suturing techniques are employed. It is imperative to use deep buried sutures to pull the retracted subcutis and muscle of the flap back to its original position along the suture line. Failure to pull this retracted tissue back to the suture line results in excess tissue under the flap, which can contract and contribute to pincushioning. This can also result in depressed suture lines that are difficult to remove with dermabrasion.

Displacement of the alar rim

The main reason for any inferior displacement of the ipsilateral alar rim is the lengthening effect of the Z-plasty. Larger angles in a Z-plasty result in greater gains in length.⁹ Thus, bulldozing is most likely to be encountered when employing larger flaps that require commensurately larger angles, and pivot within less mobile skin.¹² Since this inferior displacement is noticeable intraoperatively, the first sutures on the primary lobe can be adjusted, or the primary lobe of the flap can be trimmed. Minor displacement of the alar rim usually corrects itself by 6 weeks.¹³

Persistent erythema

Mild erythema along the suture lines is not uncommon, and spontaneously resolves by 1 month. However, persistent erythema may occur, particularly in patients with rosacea or fair skin. Neovascularization or telangiectasias may also occur in high-tension wound closures.¹⁰ These take longer to resolve, and pulsed-dye laser or intense pulsed light may be helpful.

Trapdooring and pincushioning

Undermining widely will reduce the focal scarring that can cause trapdooring or pincushioning of the inferior-most portion of the flap. Undermining to the nasofacial junction bilaterally encourages a more uniform and platelike contraction of the entire lower nose. This reduces the “puffiness” of the flap relative to the surrounding skin.

Furthermore, assure that the flap thickness matches that of the defect. This can be achieved by removing any remaining subcutaneous tissue from the

defect, and, if necessary, trimming fat from the incoming flap. The flap should be flush or slightly lower than the surrounding skin immediately postoperatively. At that point, any edema that develops around week 4 can be confidently diagnosed as simply edema due to the dependent location of the primary lobe. The patient can be reassured that this will resolve with massage and time. Infrequently, small volumes of intralesional triamcinolone may be injected to improve the scar-associated edema.

Medial canthus distortion

Infrequently, unexpected rigidity of the nasal bridge skin may be encountered, even when the patient denies previous surgery in the area. Closure of a wide tertiary defect can occasionally cause distortion of the medial canthus. This can usually be avoided by accurately assessing the degree of skin laxity prior to design, drawing the secondary lobe slightly narrower than the primary lobe, and making sure all sutures in this area are oriented precisely horizontally.

Dermabrasion

Postoperative dermabrasion is helpful in approximately one-third of cases. This can remedy any residual pits that may develop on sebaceous or rhinophymatous noses. Dermabrasion can be performed 6 weeks to 3 months postoperatively, or even later if desired.

First, hypertrophic areas are marked with a pen prior to anesthesia. Second, hypertrophic sebaceous hyperplasia surrounding the surgical lines is tangentially shaved, holding the scalpel almost parallel to the skin surface. Finally, sterilized 80-grit sandpaper is used to smooth the entire cosmetic unit. Patients apply petrolatum ointment and a nonstick bandage daily for 2 weeks, and are counseled not to allow the wound to develop a scab.

CONCLUSIONS

The bilobed flap provides a unique approach to nasal closures, as it combines the benefits of a rotation flap, transposition flap, and Z-plasty. With meticulous attention to design and execution, this technique can represent a

fundamental approach to closures on the lower nose and, occasionally, elsewhere on the head and neck.

CHAPTER 25 Island Pedicle Flaps

H. William Higgins
Samuel Book

SUMMARY

- The V-Y island pedicle flap permits a triangular island of tissue to be advanced into a defect.
- The flap relies on a robust vascular pedicle, and when properly designed is an effective technique for numerous defects.
- The chief disadvantage of this approach is the increased risk for trapdooring and resultant undesirable scarring.

Beginner Tips

- Island pedicle flaps are frequently used on the lip, as their triangular scar line may be camouflaged within cosmetic subunit boundaries.
- The fully circumferential suture lines and increased risk of trapdoor phenomenon mean that attention to detail in suturing techniques is of vital importance to camouflage the scar as effectively as possible.

Expert Tips

- Basting sutures at the base of the flap may help mitigate the risk of the trapdoor phenomenon, though care should be taken to avoid restricting blood flow to the pedicle.
- In general, island pedicle flaps should be undersized relative to the defect size.

Don't Forget!

- Undersizing island pedicle flaps means that there may be a significant component of secondary motion. This needs to be accounted for in order to avoid tissue distortion.
- Island pedicle flaps are not purely advancement flaps; they may be rotated or transposed into place as well.

Pitfalls and Cautions

- Even though island pedicle flaps benefit from a robust vascular pedicle, they should be used with caution in smokers, who may have an increased risk of necrosis.
- Always tailor flap design to the individual patient; flap elevation and undermining in patients on aspirin or other anticoagulants may increase the risk of hematoma formation.

Patient Education Points

- Patients should be warned prior to flap closure that they will have an incision stretching well beyond the initially visible defect.
- Always advise patients that they may have a multistage procedure, and that trapdooring is likely to occur. Patients will be much more understanding regarding the need for intralesional steroid injection or other intervention if they were prewarned that this may occur.

Billing Pearls

- Flap repair codes (14040 and 14060 series) should be used for V-Y island pedicle flaps, and include the excision component, so it is not appropriate to bill both an excision and a flap repair code simultaneously.
- Island pedicle flaps should not be coded with 15740, as this requires identification and dissection of a named axial vessel.

CHAPTER 25 Island Pedicle Flaps

INTRODUCTION

Defects on cosmetically sensitive locations of the head and neck require delicate reconstruction to preserve anatomic function while also providing satisfying cosmesis to the patient.¹⁻³ Options for repair range from second intention healing to complex surgical reconstruction. When chosen appropriately, flaps can provide excellent cosmesis and outcomes.⁴⁻⁶

Prior to flap repair, the surgeon should ensure that the tumor has been resected completely with clear histologic margins. Using flaps to repair the defect rearranges surrounding tissues, making it difficult to locate tumors if they recur. An incompletely excised recurrent tumor may be disguised by the flap, delaying appropriate diagnosis, which may result in increased morbidity. The rearranged tissue planes produced by the flap can also make tumor extirpation more challenging, leading to more complex surgery to remove the remaining tumor.

Once the tumor has been removed with clear histologic margins, the surgeon can consider a range of reconstructive options. A well-designed and properly executed flap provides reconstructive advantages, providing a viable vascular supply to the defect while maintaining function with minimal morbidity. The variability in skin flaps available for each type of defect requires an experienced surgeon to possess an extensive knowledge of facial anatomy, tissue motion, and reconstructive options offering the best soft tissue repair.⁷

FLAP CHOICE AND CONSIDERATIONS

After extirpation of the tumor, the defect should be examined with respect to the cosmetic units involved.⁷ Repairs that respect cosmetic units and stay within these boundaries often produce the best results. Defects that traverse more than one cosmetic subunit should ideally be repaired individually, instead of using a single repair method that crosses multiple units.^{8,9}

Flaps are typically categorized based on the type of movement involved, such as advancement, rotation, transposition, or interpolation; or by the blood supply pattern, for example, random or axial. Random pattern flaps are supplied by dermal vasculature, while axial pattern flaps are supplied by named vessels; the former are more frequently performed in dermatologic surgery.

Description of the V-Y island pedicle flap

The island pedicle flap, also referred to as the V-Y advancement flap, is a specialized type of advancement flap. This modified advancement flap uses a triangular or V-shaped section of skin to repair the primary defect. With the flap in place, the resulting incision lines appear in the shape of a Y. When creating the flap, a triangular shaped skin segment is completely separated from surrounding skin, creating an island. Despite being detached from surrounding structures, an underlying supply of rich vasculature embedded in the subcutaneous tissue remains intact, forming a pedicle.

This repair is a valuable and versatile tool for use on head and neck defects. Its rich vascular pedicle, combined with the enhanced mobility of the island, makes it a workhorse flap for many small- to medium-sized defects in cosmetically challenging areas of the face. It is unique in that its vascular supply relies entirely on the underlying pedicle, as all epidermal and dermal margins are severed when creating the island. Subsequently, the triangular island can be advanced as far as the underlying mobility allows. This unique characteristic allows the surgeon to take advantage of neighboring tissue reservoirs with more freedom than a traditional advancement flap, in which motion is restricting by the adherent margin of the flap (restraint).

The single-stage repair also offers predictable aesthetics with minimal morbidity or operative risk. This flap was initially described for use on cutaneous defects of the forehead, eyebrow, nasal dorsum, cheek, and upper cutaneous lip. Modified versions of this flap have also been used to

reconstruct challenging defects of the ear, medial canthus, nasal ala, and nasal tip.^{10–18} Because the resulting flap leaves a tail-shaped outline, analogous to the lower half of a Y, the incision lines of the flap can often be hidden along contour lines, rhytides, or cosmetic subunit boundaries.

Comparison to traditional advancement flap

Traditionally, the mechanics of an advancement flap require that it have a length-to-width ratio of approximately 3:1. This allows for adequate perfusion of the entire flap, as well as optimizing wound tension. Flaps exceeding this ratio have a higher risk of distal necrosis due to poor perfusion. This ratio can be limiting in certain situations, as the surgeon must choose between widening the width of the flap to accommodate the length, with resulting worsening cosmesis, or lengthening the flap without changing the width, with risk of distal necrosis.^{14,15,19}

As with classic advancement flaps, the island pedicle flap has a tension vector that is parallel to the direction of the flap. Like all flaps, the tension caused by advancement of the island pedicle can lead to secondary movement of the skin distal to the flap. This secondary movement is important to consider, as it can lead to distortion of cosmetic unit boundaries or altered anatomic function in areas such as the eyelid margin or nasal ala.^{14,15,19}

Advantages of the island pedicle flap

Compared to other random axial flaps or traditional advancement flaps, the island pedicle flap has several advantages (Table 25-1). The pedicle provides an excellent vascular supply, as it relies on the rich subcutaneous plexus. In contrast, other flaps depend on dermal anastomoses and are thus at higher risk of necrosis. In the case of a traditional advancement flap, the blood supply originates from the base of the flap, and is dependent on dermal vasculature spanning the entire length of the flap to provide blood supply to the distal edge.^{20,21}

Table 25-1. Advantages and Disadvantages of the Island Pedicle Flap Compared to Traditional Advancement Flaps

Advantages	Disadvantages
Excellent vascular supply from subcutaneous and dermal plexus in the pedicle	Resistance to movement with increased wound tension
Even perfusion pressure throughout pedicle	Increased time for suturing
Decreased risk of flap necrosis	Trapdooring
Decreased need for undermining	Difficult to hide all aspects of the scar within relaxed skin tension lines
No limitation on width to height ratio of flap	Bulkiness of pedicle
Mobility	
Does not require resection of standing tissue cones	

The island pedicle flap is not limited by the 3:1 ratio of advancement flaps, since the vascular supply originates from the rich underlying tissue. Larger flaps can, therefore, be designed with minimal risk of tissue necrosis. Since the subcutaneous tissue supplies the skin evenly, the perfusion pressure is equivalent throughout the pedicle, obviating the traditional increased risk of distal flap-tip necrosis. This reliable blood supply provides a significant advantage compared to other random pattern flaps, and may be a good choice for patients with poor perfusion status, such as chronic smokers, or those with areas of poor vasculature due to prior surgery or radiation in the defect area.

The island pedicle also requires less undermining compared to many other flaps. Since the deep aspect of the pedicle remains connected to the underlying subcutaneous fat, this portion of the flap does not require undermining. This provides an advantage for patients at high risk of bleeding, such as those with thrombocytopenia, bleeding diatheses, or using anticoagulants.

Cosmetically, the tail of the flap can also be incorporating into rhytides or cosmetic subunit boundaries, thereby improving the aesthetic result (Figs. 25-1 and 25-2). For example, in the upper lip area, the tail of the flap produced by closure of the secondary wound can be placed within the fold of the nasolabial groove, providing a minimally noticeable result.²²

Figure 25-1. The flap can be incorporated into cosmetic subunit boundaries.

A

B

C

D

Figure 25-2. Even for larger defects, parts of the suture line may be designed to rest along cosmetic subunit boundaries.

Disadvantages of the island pedicle flap

Despite the many advantages of the island pedicle flap, it does have several disadvantages ([Table 25-1](#)). Although the pedicle provides an excellent vascular supply from the subcutaneous plexus, this connection to the deep tissue often results in some resistance to movement. This can increase tension on the flap and also necessitate more reliance on secondary tissue movement. Thus, a pedicle used for large defects will have increased tension at the wound closure site. Using a smaller pedicle allows for decreased tension and improved mobility, but this is offset by the potentially decreased vascular supply of the smaller subcutaneous plexus.

Furthermore, due to the island design, the tissue is incised around the entire margin of the flap. This may increase the risk of trapdooring, which occurs when the flap heals with slight contraction, causing the skin of the flap to rise above the surrounding skin. Trapdooring creates a noticeable and often cosmetically distressing change in skin texture for many patients. This may be ameliorated with dermabrasion, intralesional steroid injection, or surgical revision, though it often improves spontaneously over time.

The incisions of the island pedicle flap also produce a “V” shape, which may make it difficult to hide all of the sides of the flap within natural skin tension lines. In certain locations, such as the upper lip, this task may be easier, with lines along the nasolabial fold, alongside the white roll of the vermillion border, or along the alar crease. In other locations, such as the cheek, this task may be more difficult. This flap also requires meticulous suturing since the entire pedicle is separated on all sides and must be repositioned to fill the defect. Thus, extra time for suturing may be needed for the novice dermatologic surgeon.

Design

Choosing the appropriate wound and location is the first step to success when executing this flap. It is important to assess the amount of mobility that will be produced when circumferential margins of the island are severed. Although this flap can be used for defects ≥ 2 cm in diameter on cosmetically sensitive areas such as the nose or upper lip, the island pedicle flap is typically suited for small- to medium-sized wounds on these areas. The nose has stiff skin and typically lacks the compliance and pliability of other areas such as the cheek. Moreover, due to the curvature of the numerous nasal cosmetic subunits, secondary motion may lead to cosmetically undesirable nasal asymmetry.

Proper design is crucial to the execution and outcome of the island pedicle flap, and allows the surgeon to achieve optimal and reproducible aesthetic results with minimal risk. In general, the flap is designed as an isosceles triangle with two longer edges (the sides) and one shorter edge (the base). The long axis of the flap is ideally placed in relaxed skin tension lines and may be curvilinear to match areas such as the melolabial fold or the vermillion border. This allows the healed incision scars to hide within natural skin folds, making them less cosmetically distressing.

In its classic design, the flap is incised adjacent to the defect and within the same cosmetic subunit (Figs. 25-3 and 25-4). The flap is oriented tangentially away from the defect. The length of the triangular pedicle is usually three to four times the width of the defect, with the apex of the isosceles triangle is angled at roughly 30 degrees. Incisions around the triangular island are made to the level of the subcutaneous fat. The pedicle is also incised with vertical incisions deep to the subcutaneous tissue and may contain muscle or superficial musculoaponeurotic system (SMAS) elements. The surgeon should be comfortable with anatomical variations of structures, and particularly vessels in all layers of the subcutaneous tissue. Even if the flap is overlying a named vessel, this vessel is not dissected with the flap, as the pedicle provides a rich enough vascular subcutaneous plexus to maximize chances of flap survival.

Figure 25-3. Classically, the flap is designed to stay within the same cosmetic subunit.

Figure 25-4. The tail of the flap may ideally be hidden along cosmetic subunit boundaries.

Critically, the flap should be slightly undersized for the defect.¹⁵ Thus, the width of the flap is ideally slightly smaller than the width of the defect. This requires secondary movement of tissue around the defect, but reduces the risk of flap protuberance after it has healed. Basting sutures may also be used to mitigate the risk of trapdoor formation.

The flap is next undermined along the edges, but not at the base of the pedicle. The surrounding skin of the primary surgical defect is also undermined at the same level. The tissue of the pedicle is left intact without excessive undermining to allow for adequate, random pattern perfusion from the subcutaneous plexus. If inappropriately undermined, the flap is at risk of failing due to a compromised vascular supply needed to nourish the tissue. The pedicle itself can contain epidermis, dermis, subcutaneous tissue, fat, muscle, and parts of the SMAS. Undermining of the surrounding edges is performed above the superficial fascia, allowing for adequate movement. This minimizes tension with wound closure and helps to prevent inversion caused by pull at the leading edge. In some areas, such as along the eyelid

margin, the secondary motion created by the flap can cause undesirable functional or cosmetic results, such as ectropion.

After freeing the island, the flap should be advanced forward into the primary defect in a V-Y manner. While advancing the flap, secondary tissue movement will be necessary, especially given the bulky nature of the pedicle. This motion of pulling the flap forward also allows the surgeon to visually determine which aspect of the flap requires more mobility. If the surgeon places a finger on the pedicle during movement, the remaining vectors of resistance may be determined and additional undermining may be performed to free up movement in this vector. The narrow tail of the flap is often an area that requires additional undermining to lessen restriction on the advancement of the pedicle. Aggressive undermining of the apex, or the tail, can significantly improve the mobility of the flap.

If the pedicle itself requires undermining, this is done with extreme care. The surgeon should test flap mobility after each step of undermining to minimize over-undermining the pedicle and compromising its vascular supply. Usually, the leading edge of the flap is also undermined, but to a lesser degree than the tail.

The key suture of this flap is placed in the deep dermis at the midpoint of the leading edge and the corresponding point of the defect. Buried vertical mattress or set-back sutures are ideally used.¹⁵ Tip stitches for the apex of the flap are generally not necessary. Basting or quilting sutures may be used to tack down the body of the flap, though care should be taken to avoid ligating the flap's vascular supply. After all dermal sutures are placed, the elevation of the pedicle should be lower than that of the surrounding skin, perhaps by as much as 2 to 3 mm. With wound contraction and healing, the pedicle will elevate relative to the position of the surrounding skin.

Due to the nature of the design with free margins on all sides of the pedicle, this flap is particularly susceptible to the trapdoor phenomenon, producing a protuberant aesthetic appearance (Fig. 25-5). This complication commonly develops early during the postoperative period, and occurs more often on the medial cheek or lip. Undersizing the flap will help to minimize the trapdoor deformity, although this requires secondary motion of the edges surrounding the defect. The surgeon must account for and predict this secondary motion in order to properly execute the flap.

Figure 25-5. Pincushioning, or the trapdoor phenomenon, is classically seen with this design.

The classic locations chosen for repair using the island pedicle flap include the upper lip. Other areas for which this flap can be used include the upper brow/temple, lateral upper lip, medial cheek ([Fig. 25-6](#)), upper nasal dorsum, and alar groove. Some of these locations may require the use of a modified flap design.

Figure 25-6. This flap may be used beyond the lip and nose, and cheek defects can be reliably reconstructed as well.

FLAP MODIFICATIONS

The island pedicle flap is an excellent reconstructive option that allows for consistently reproducible results. Several design modifications have been introduced to accommodate defects in certain locations or other limitations to using the traditional design of this flap. While the central pedicle provides an excellent vascular supply, the bulkiness of this pedicle can sometimes impede flap mobility. Thus a modification using a laterally based pedicle may improve flap movement while also allowing for adequate perfusion. Dual island pedicle flaps can also be employed, with pedicles of differing sizes.

Unilateral island pedicle or single lateral island pedicle flap

This variation of the traditional island pedicle flap can be beneficial for nasal tip and alar defects. Unlike the conventional design, which maintains a central subcutaneous tissue pedicle, only one lateral edge remains attached while the rest of the pedicle is detached from the subcutaneous tissue. This laterally based pedicle can be comprised of subcutaneous fat or a muscular sling. This modification allows for even greater flap mobility, as the tissue can be more easily advanced or rotated into the defect. When used for defects on the distal nose a lateral pedicle based on the nasalis musculature may be employed, which allows for more predictable perfusion. In locations where nasalis muscle cannot be incorporated, a wider pedicle of laterally based subcutaneous tissue can be recruited.²²

Dual (“bilateral,” “double,” or “bi-pedicled”) island pedicle flaps

Dual island pedicle flaps are used in cases where a single island pedicle cannot be adequately mobilized to reach the distal edge of the defect. This repair can also be used for defects consisting of different tissue types, such as those involving both the upper cutaneous lip and mucosal lip.²³ Dual island pedicle flaps may advance from opposite sides, or in opposite directions (horizontal and vertical).

In one variation, Huilgol et al. conducted a review of 10 patients with defects involving both the upper cutaneous lip and mucosal lip.²³ Using cutaneous upper lip skin and mucosal skin, two island pedicle flaps were designed to fill their respective defects. Once the pedicles were in position, the advancing edges were trimmed to simulate the shape of the vermillion/upper lip boundary. Cosmetic results were excellent. This variation may also be used on the scalp.

Shark island pedicle

The shark island pedicle is a useful modification for combined defects that span the ala and perialar cheek. Its advantage is that it provides a single-stage option that preserves the complex contour of the concave cheek–nose junction. While designed in similar fashion to the traditional island pedicle flap, its descriptive name is due to its leading edge having a similar

appearance to the mouth and snout of a shark. The superior arm of the flap rotates 90 degrees to repair the alar aspect of the defect while the remainder of the advancing pedicle repairs the cheek up to the nasofacial sulcus.

Tunneled island pedicle flap

This modification can be used when the defect and flap pedicle are not immediately adjacent to each other. It allows for preservation of normal tissue in between the flap and the defect. The flap “tunnels” underneath this portion of normal skin to fill the defect.²⁴⁻²⁶

In one example, Wang et al. used the tunneled island pedicle flap to reconstruct an earlobe with preauricular skin, while preserving the normal section of tissue at the medial edge of the earlobe. This tissue separated the defect from the flap. A “tunnel” was created underneath this medial edge, allowing for the pedicle to pass through it to reach the defect. This allowed for a good match of the fibrofatty tissue of the earlobe, thus restoring the normal contour and texture of this tissue location.²⁶

The advantage of this flap modification is that it allows for defects to be repaired in a single stage and preservation of normal tissue. The disadvantage of this flap modification is that it increases the risk of trapdoor phenomenon and may add bulkiness to the intervening normal skin.

Transposition island pedicle flap

This modification of the island pedicle flap, in which the pedicle is transposed at a 30- to 120-degree angle, can be useful in repairs of the medial canthus or lateral nasal ala.^{27,28} For defects of the medial canthus, the glabellar tissue reservoir is used to create the island, which is transposed into the defect. Closing the secondary defect helps with accurate positioning of the pedicle. For the nasal ala, the transposition island pedicle flap can use the reservoir of tissue in the nasolabial fold to create the pedicle used for the defect.

This flap has several advantages, including the ability to avoid the standard pivot-related restraint of transposition flaps, the ability to have the secondary defect not immediately adjacent to the primary defect, the option of using a single-stage flap instead of a two-stage flap, and a superior

vascular supply compared to other transposition flaps. The bulkiness of the flap can also be used to the surgeon's advantage for deep defects in the nasal sidewall or nasal root, or for the recreation of the ala. However, the bulkiness of the flap can also pose as a disadvantage, as it can predispose to trapdooring, result in nasal fullness or protrusion which restricts airflow, and the possibility that stretch and trauma to the pedicle during transposition may cause tip necrosis.

Multistaged island pedicle flap

The two-stage island pedicle flap, described as the cheek island pedicle flap, is a useful alternative to the paramedian forehead flap for substantial defects of the lower nose.²⁹ Here, an island of tissue is recruited from the nasolabial fold, and undermined. The pedicle is ideally left at the superior pole of the flap, and the flap is rotated over intervening normal skin to cover the defect. The secondary defect is closed primarily, and flap take-down occurs at approximately week 3 (Table 25-2).

Table 25-2. Pearls in Island Pedicle Flap Design

For the nose, chose small- or medium-sized defects (Figs. 25-7 and 25-8)
Undersize the pedicle
Evaluate mobility of pedicle during movement by palpating the flap while advancing it forward into the defect
When undermining the pedicle, test mobility after each incision to lessen the likelihood of compromising the underlying vascular support
Ensure that the pedicle is recessed in relation to surrounding skin after deep sutures are placed to lessen the risk of trapdoor phenomenon

A

B

C

Figure 25-7. The ideal nasal defect is fairly small.

A

B

C

Figure 25-8. While larger defects may be closed with this technique as well, they run an increased risk of pincushioning, though this may be a valid tradeoff if the suture lines are hidden in cosmetic subunit boundaries.

CONCLUSIONS

The V-Y island pedicle flap, also known as a V-Y advancement flap, is a useful flap that benefits from a robust vascular supply. This random pattern flap can be used in a variety of locations, either as a classic or modified island pedicle flap. The excellent vascular supply and ability to use adjacent or nearby skin to repair the defect allow for predictably excellent cosmetic results, with good color and texture match. Its main disadvantage is the risk of the trapdoor phenomenon, which may be mitigated by precise layered suturing techniques, basting sutures, and undersizing the flap.

CHAPTER 26 Interpolation Flaps

Rachel Redenius

Jeremy S. Bordeaux

SUMMARY

- Interpolation flaps are very effective for large or deep defects, as their robust vascular supply allows closure of distant defects.
- Most interpolation flaps require at least two stages, and the degree of local care and functional and cosmetic compromise between stages means that appropriate patient selection is of vital importance.
- The paramedian forehead flap is the most frequently used interpolation flap in dermatologic surgery, though cheek- to-nose, paranasal, postauricular, lip, and eyelid interpolation flaps are used as well.

Beginner Tips

- The surgeon should precisely design a template that accounts for the three-dimensional shape and contour of the nose.
- Doppler localization of the underlying axial vessel may not be needed.
- It is best to match the thickness and contour as much as possible during the initial inset, though a delicate balance must be maintained as aggressive thinning in the first stage may increase the risk of ischemia.

Expert Tips

- The Abbé flap may result in difficulty with eating or speaking prior to flap division.
- This flap may also appear markedly edematous for up to a year postoperatively, and no revisions should be attempted prior to 6 months to allow this swelling to resolve. Sensory and motor functions are affected during the procedure and it may require a year or more to regain complete neuromuscular function.
- The three-stage paramedian forehead flap may provide a superior cosmetic outcome, though an additional surgical procedure is required.

Don't Forget!

- An oversized flap, or a flap that has not been appropriately thinned, may require a revision with another surgery, intralesional steroids, dermabrasion, or laser.
- Necrosis may be seen more often with the cheek-to-nose flap compared to other interpolation flaps due to its less robust blood supply.

Pitfalls and Cautions

- All patients should be counseled that additional revisions such as dermabrasion or contouring may be required at a later date.
- For the Abbé flap, patients should be appropriately counseled regarding the anticipated difficulty with eating and speaking prior to pedicle division.
- Lymphedema lasting many months is common after eyelid interpolation flaps.

Patient Education Points

- From the patient's perspective, staged interpolation flaps are among the most challenging closures in dermatologic surgery, as they must care for and endure an unsightly pedicle for several weeks postoperatively.
- Paresthesias secondary to transection of the supratrochlear nerve can be permanent, and patients should be counseled about this prior to surgery.

Billing Pearls

- Interpolation flaps on the nose, eyelids, and lips are coded with 15576 at the time of pedicle formation and 15630 at the time of takedown.
- Like all flap codes, there is a 90-day global period associated with these codes.

CHAPTER 26 Interpolation Flaps

INTRODUCTION

A large, complex facial defect may create permanent disfigurement and significant psychological morbidity. While cosmetic expectations differ among patients, all desire to retain a normal-appearing face. Surgeons have many reconstructive options, and their selection is based on the size, location, and depth of the defect.

A properly executed local flap is one of the most reliable options for restoring cosmesis and function. When local random pattern flaps are unable to repair a defect, the surgeon may consider using an interpolation flap, a highly effective technique for large or deep defects. They can be supplied by a named artery (axial pattern flap) or by a rich vascular plexus (random pattern flap), and their robust blood supply allows them to repair distant defects. Interpolation flaps generally require two or more stages for completion, though single-staged variants have been described.¹ During the first stage, the surgeon transfers the flap into the defect, leaving the vascular supply attached to its pedicle. During the second stage of the procedure, approximately 3 to 4 weeks later, the pedicle is divided, and the flap is inset. Given the complexity of these repairs, and the need to care for a cosmetically unsightly pedicle until takedown occurs, appropriate patient selection is essential.

An extensive preoperative conversation should take place between the surgeon and the patient when an interpolation flap is anticipated. The surgeon should assess what is required to repair the defect, the limitations of the patient's anatomy, and whether this type of flap is reasonable for this particular patient. The patient should have a driver present and have someone at home to assist with wound care. Photos of prior repairs can be shown to the patient and caregiver to help them visualize and comprehend the

procedure. Some patients may not wish to undergo a multistage procedure, and the surgeon must always balance the complexity of the procedure (and attendant postoperative care) with the desire for a perfect reconstruction. All available alternatives should be discussed with a patient, even if they provide inferior cosmetic and functional outcomes, to allow the patient to make an informed decision. Certain social situations may preclude the use of interpolation flaps, and other reconstructive options should be considered for patients who live alone or for those who suffer from decreased mental status and may manipulate the repair prior to the second stage.

PARAMEDIAN FOREHEAD FLAP

The paramedian forehead flap (PFF) is a resilient, highly vascularized flap that is best used to repair large, complex defects on the nose. The sebaceous skin on the forehead provides a suitable color and texture match for this area, and the vascularity of the pedicle allows the flap to reach considerable distances. It is traditionally based on the supratrochlear artery, which lies approximately 1.5 to 2 cm from the midline of the glabella. The supratrochlear artery exits the supratrochlear foramen, crosses the corrugator supercilii, and pierces the frontalis muscle just above the level of the orbital rim. It continues to ascend vertically in the subcutaneous tissue.

Flap design

When designing any flap, it is important to consider function, free margins, and form. The PFF cannot simply be placed on the distal nose without proper structural support to prevent collapse of the nasal valve. Cartilage grafts provide structural support, prevent alar retraction, and also help to restore the normal form and contour of the nose.^{2,3} The grafts are often harvested from the conchal bowl or antihelix for convenience, though nasal septum and costal sources can also be considered. If the nasal lining is not intact, mucosal flaps, hinge flaps, bipedicle septal flaps, or inverted full-thickness skin grafts can be used.⁴⁻⁷ A three-stage fold-over PFF is an excellent option for repair (Fig. 26-1A,B).

Figure 26-1. (A,B) Recreating the intranasal lining using a three-stage fold-over paramedian forehead flap.

For defects involving >50% of a cosmetic subunit, enlarging the operative wound to encompass the entire subunit may provide a superior aesthetic outcome. A template of the defect is made using gauze, Telfa, steri-strips, or foil from a suture packet prior to excision of the remaining subunit (Fig. 26-2). The template is then rotated 180 degrees onto the forehead (Fig. 26-3). The contralateral forehead is often chosen for the flap as this rotates with less torsion. If the defect is midline, either side of the forehead can be used, and laterality is decided based on the quality of the skin and the lack of any other local suspicious lesions. The distance from the anterior hairline to the superior orbital rim is measured to determine the length of the flap (Fig. 26-4A,B). If the reach is not adequate, the flap may extend onto the scalp or below the superior orbital rim. A paramidline flap design located 1.2 cm lateral to the midline of the glabella may be beneficial when longer flaps are needed, as extending the pedicle inferiorly does not affect the brow.⁸ Extension onto the scalp will transfer terminal hairs to the nose, though this should not prevent the use of this repair, as creating a normal-appearing nose takes precedence. The flap can be thinned distally to remove hair follicles, or the patient can shave, epilate, or undergo laser hair removal or electrolysis postoperatively.

Figure 26-2. A three-dimensional template is created using steri-strips.

Figure 26-3. The template is inverted onto the forehead. The pedicle is marked 6 mm to each side of the most prominent corrugator crease.

A

B

Figure 26-4 (A,B) The distance from the base of the pedicle to the top of the template is measured with gauze. The gauze is then rotated toward the nose to confirm flap reach.

The vascular supply of the pedicle is based on the supratrochlear artery, which may be determined based upon anatomical landmarks or using a handheld Doppler ultrasound. No difference in flap survival or complications was seen when comparing these two techniques.⁸ The most prominent glabellar frown line and 6 mm of lateral skin reliably corresponds

to the location of this artery, and can be used in lieu of Doppler localization.⁹ The width of the pedicle is rarely greater than 1.5 cm, as wider pedicles may limit the flap's mobility and impair blood supply due to greater torsion and compression of the artery.

Flap elevation

If the defect extends to other cosmetic subunits, such as the cheek, it is best to repair these separately in order to maintain the natural cosmetic boundaries of the face. After extranasal portions of the defect have been repaired, the forehead is prepped in a sterile fashion and anesthetized. An incision is made on the superior forehead in a subcutaneous plane. The templated portion of the flap is elevated more superficially to minimize the need for pre-inset debulking. Once this distal portion has been elevated, the level of dissection should transition to a deeper plane, just above the periosteum. Including frontalis muscle (and possibly galea) in the pedicle of the flap minimizes the risk of transecting the supratrochlear artery and ensures an adequate vascular supply.¹⁰ Once elevated, the flap should drape over the defect without tension (Fig. 26-5).

Figure 26-5 The flap drapes over the defect with no tension.

Flap inset

The edges of the defect are squared off to receive the flap, and the flap is thinned to match the defect. Flap thinning and contouring can be delayed if adequate vascularity is a concern, such as in a smoker. Cutaneous or dermal sutures are used to secure the leading edge of the flap to the defect.

Donor site closure

The forehead should be undermined in a subgaleal plane and meticulously closed to prevent an inverted scar. An excessively tight closure should be avoided, and second intention healing may be required if complete closure is not possible ([Fig. 26-6](#)).

Figure 26-6. The forehead defect cannot be completely closed primarily and is left to heal by second intention.

Postoperative instructions

Pinpoint electrocoagulation may be used along the pedicle to provide hemostasis, though the area often continues to ooze postoperatively as the epinephrine effect wears off. Wrapping the pedicle in oxidized regenerated cellulose gauze (Surgicel, Ethicon, Inc., Somerville, NJ) may help reduce

bleeding.¹¹ A bulky pressure dressing is placed which may obstruct peripheral vision and prevent the patient from wearing glasses (Fig. 26-7). Having a driver is therefore necessary. The patient returns in 1 week for a dressing change.

Figure 26-7. Pressure dressing in place following paramedian forehead flap.

Second stage

Three weeks later, the patient returns for pedicle division and distal flap thinning. The pedicle is first cut at the base. The entire stump can be excised and repaired with a linear closure, or inset with a V-Y repair. Incisions are recreated along the original wound, and the flap is thinned and sutured into place (Fig. 26-8A,B).

Figure 26-8. (A) Patient returns at 1 month for flap takedown. (B) Completion of the second stage.

Technique pearls

The surgeon should precisely design a template that accounts for the three-dimensional shape and contour of the nose (Fig. 9A,B). It is best to match the thickness and contour as much as possible during the initial inset, though a delicate balance must be maintained as aggressive thinning in the first stage may increase the risk of ischemia. An oversized flap, or a flap that has not been appropriately thinned, may require a revision with another surgery, intralesional steroids, dermabrasion, or laser. This is often addressed 4 to 6 months from flap takedown.

Figure 26-9. (A,B) The three-dimensional template is carefully removed to keep its shape. Relaxing incisions are made to flatten the template prior to transferring onto the forehead.

Surgeons should also devote time to repairing the secondary defect on the forehead to prevent a noticeable, inverted scar. If tension is too great, the area should be left to heal by secondary intention.

Paresthesias secondary to transection of the supratrochlear nerve can be permanent and patients should be counseled about this prior to surgery.

Necrosis is rare given the reliable blood supply to this flap, though it may occur in the setting of extreme tension or if the patient is a heavy smoker. Superficial slough can be removed at the time of division and left to heal by secondary intention. In the catastrophic event of complete flap failure, observation is recommended. The pedicle will autoamputate and revisions can be performed at a later date if needed. In general, this flap approach is reliable and leads to excellent aesthetic and functional outcomes (Fig. 10A–M).

(M) Postoperative appearance at 1 month (inferior view).

CHEEK-TO-NOSE INTERPOLATION FLAP

The cheek-to-nose interpolation flap (CIF), or melolabial interpolation flap, is a random pattern flap based on tributaries from the angular artery. It is best used for deep defects isolated to the nasal ala.^{12–15} The flap derives from the sebaceous skin of the medial cheek, which provides a good color and texture match for this area, and the donor site scar is camouflaged in the melolabial fold. One disadvantage of this flap is the potential transfer of terminal beard hairs in men. This can be addressed through thinning of the flap or postoperative hair removal as described above for the PFF.

Flap design

Loss of muscle in the nasal ala reduces structural support, and a cartilage graft is often required to prevent nasal valve collapse, maintain airway patency, prevent contraction of the alar rim, and provide bulk to restore the natural alar convexity.² Pushing against the alar rim to detect resistance and watching for alar collapse as the patient inspires can be helpful to gauge the need for additional support.² If vestibular lining is required, the flap can be designed to fold over onto itself, though a PFF may be better suited for these larger, full-thickness defects. A template is made of the defect, often using the contralateral ala as a reference. The template is then rotated onto the cheek so that the superior portion lies along the melolabial fold and the inferior portion lies laterally. Burow's triangles are drawn above and below the template to create an ellipse. Flap reach is confirmed with a suture or stretched gauze, ensuring that neither is stretched too tightly. Always overestimate flap length.

Flap elevation

The flap is incised and elevated at the level of the subcutaneous fat on its distal edge. Some surgeons may transition to a deeper plane when approaching the proximal pedicle to include muscle fibers from the levator labii superioris alaeque nasi, which increases the vascular supply. The pedicle can retain attachments to the cheek at the superior portion of the most proximal Burow's triangle (peninsula), or it can be freely mobilized on its subcutaneous pedicle. The former increases the vascular supply, while the latter reduces torsion and allows for easier division and inset. The flap is

lifted and rotated counterclockwise for a right-sided defect or clockwise for a left-sided defect. It should cover the defect with no tension.

Flap inset

The distal portion of the flap is thinned as needed to match the defect. The edges of the defect are squared off and prepared to receive the flap. Undermining the nasal skin may help prevent pincushioning. The flap is secured with cutaneous and dermal sutures. The alar crease should be left to heal by the second intent, tacked down, or sutured with inverting sutures to maintain the concavity.¹⁶

Postoperative instructions

Dressings are less cumbersome than for the PFF, as the patient may drive and wear glasses. The exposed pedicle is gently cauterized and wrapped with Surgicel or Xeroform gauze. A pressure dressing is left in place for 24 to 48 hours. The patient returns 1 week later for dressing change.

Second stage

The pedicle is divided 3 weeks later, starting with the base. If the pedicle maintained attachments to the cheek, the entire base of the pedicle must be excised with an ellipse and repaired with a layered closure. If the base was unattached, it may be inset back into the cheek with a V-shaped incision or similarly removed with an elliptical excision. The flap can also be additionally thinned at this time if needed.

Technique pearls

Flattening of the melolabial fold occurs as a result of this flap, though this is usually mild and not bothersome to the patient. If needed, an elliptical excision of the contralateral melolabial fold can recreate symmetry.

Necrosis may be seen more often with the CIF compared to other interpolation flaps due to its less robust blood supply. When this occurs, it most often involves the distal edge of the flap which can be left to heal by

secondary intention. These flaps also have a tendency to pincushion, which may be of benefit to restore the convexity of the ala. If it is problematic, intralesional triamcinolone can be used starting approximately 1 month after takedown. All patients should be counseled that additional revisions such as dermabrasion or contouring may be required at a later date (Fig. 11A–G).

(D) Flap survival at 3 weeks. (E) Pedicle division and inset. (F) Postoperative appearance at 6 months (oblique view). (G) Postoperative appearance at 6 months (frontal view).

PARANASAL INTERPOLATION FLAP

The paranasal interpolation flap (PIF), a variation of the CIF, is a random pattern flap derived from the lateral nasal sidewall and nasofacial sulcus.¹⁷ Since this is a nonhair-bearing area, this flap can prevent the transfer of facial hair to the nasal ala as may occur with the traditional CIF in men. Another advantage of this location is that the pedicle has a smaller axis of rotation, which causes less torsional strain and requires a shorter flap. The donor site location also prevents the flattening and asymmetry of the melolabial fold observed with the traditional CIF. This flap is best used for small- to medium-sized defects isolated on the nasal ala. Patients with excessive lower eyelid laxity are not good candidates for this repair due to the risk of ectropion.

Flap design

A template of the defect is created using the contralateral ala as a reference. The width of the flap should equal the vertical height of the defect, and an ellipse is created surrounding the template. If needed, a cartilage graft can be harvested prior to flap elevation and placed as described previously.

Flap Elevation

An incision is made just lateral to the ala and continued superiorly into the melolabial fold and nasofacial sulcus. This represents the medial portion of the flap and another incision is made laterally to parallel this. The flap is elevated just below the dermis. Transitioning to a deeper plane occurs as the base of the pedicle is approached to preserve the vascular plexus.

Flap inset

The flap is rotated into place under no tension, secured with buried and cutaneous sutures, and trimmed as needed. The donor site on the cheek is undermined and closed primarily. Lower eyelid tone should be carefully assessed during this closure to avoid ectropion.

Second stage

The patient returns 3 weeks later for division and inset. The pedicle is divided lateral to the defect and the flap is appropriately thinned. The edges of the defect are freshened, and the flap is sewn in place. The base of the pedicle is excised with an elliptical excision, undermined, and closed primarily.

Technique pearls

Revisions such as laser, dermabrasion, intralesional Kenalog, or additional surgeries may be needed at a later date as previously described (Fig. 12A–G).

POSTAURICULAR INTERPOLATION FLAP

Wounds that involve the helical rim can be challenging to repair without altering the shape of the ear. When perichondrium is intact, a full-thickness skin graft may effectively restore cosmesis. This is not suitable, however, if only cartilage remains in the wound bed. Though cartilage may eventually heal by secondary intention, there is an increased risk of infection, inflammation, and destructive chondritis. Random patterned, pedicle flaps from the posterior ear provide a reliable alternative for large defects involving the helix and anterior ear.^{12,14,18} This repair produces a highly aesthetic result that maintains ear size and contour. Additionally, the donor site is hidden from view and heals very well.

Flap design

The location for the flap is selected on the postauricular skin. A template of the defect is made and transferred to the donor site. The ear should be folded back to the mastoid process and the vertical height of the defect measured to ensure the flap is not undersized. Depending on the size of the wound, the pedicle can involve only the mastoid process or may extend to the postauricular sulcus and posterior ear. A preauricular donor site or other reconstructive options may be considered when patients have a hairline abutting the postauricular sulcus, to prevent the transfer of terminal hairs onto the ear.¹⁴

Flap elevation and mobilization

An incision is made along the anterior border and both sides of the flap. The skin is elevated above fascia at the mastoid process or above perichondrium on the posterior ear and postauricular sulcus. The distal portion of the flap may be thinned, but a thin layer of adipose should remain on the flap to ensure viability. Meticulous hemostasis is important because visualization

will be difficult after the flap is placed. The flap is then draped over the defect. Both the primary and secondary defects can be undermined slightly to increase mobility.

Flap inset

The flap is sutured into place with cutaneous sutures starting at the anterior surface of the ear and extending to the helical rim. Basting sutures can be used to recreate the natural contour of the helical rim. This can be accomplished during the first or second stage, but may be easier during the first stage since wound contraction can cause flattening of the pedicle.¹⁸ If a full-thickness defect is present, the flap can be folded onto itself to recreate the helical rim. A cartilage graft is rarely needed in this instance unless a large portion of the cartilage is missing. This flap is broad-based and placed without torsion, so it can tolerate some tension without compromising vascularity; minimal to no tension should exist if properly sized.

Postoperative instructions

Patients often tolerate this procedure very well, as the pedicle is camouflaged behind the ear and they can wear glasses and hearing aids after the initial pressure dressing is removed in 24 to 48 hours. Continued drainage from the pedicle is a nuisance for many patients, and this should be discussed preoperatively. Packing or a penrose drain may be inserted in the postauricular tunnel to mitigate this concern. The dressing is changed 1 week later.

Second stage

The patient returns 3 weeks later for division of the pedicle. The stump can be removed entirely, leaving the secondary defect on the mastoid or posterior ear to heal by secondary intention. Alternatively, the wound edges can be freshened and the pedicle returned to its original position. The remaining flap is thinned as needed and sutured into place. Vertical mattress sutures can be helpful where the flap crosses the helical rim to prevent notching.

Technique pearls

Like all interpolation flaps, it is important to accurately measure the distance the flap needs to travel to reach the defect. In the case of the postauricular interpolation flap, the defect can extend onto the posterior ear if additional reach is needed.

Blunting of the helical rim can occur with this repair. While this does not bother some patients, folding the flap over and using basting sutures can help recreate the helical rim. Blunting of the scaphoid fossa, caused by bridging between the helical rim and antihelix, can also be prevented by the use of basting sutures.

Eversion is most important on the helical rim to prevent notching, and vertical mattress sutures can be helpful in this location (Fig. 13A–G).

ABBÉ FLAP

The Abbé flap (or lip-switch flap) is an axial patterned flap based on either the superior or inferior labial artery.^{19,20} It is used to repair large, full-thickness defects involving 1/3 to 1/2 of the upper or lower lip, and involves the transfer of skin, muscle, and mucosa. It has also been used in cleft lip repair.²⁰ This repair should not be used for defects involving the oral commissure. Both the inferior and superior labial arteries originate from the facial artery near the oral commissure, and anastomose with the opposite side to encircle the lip. They are typically found between the oral mucosa and orbicularis oris muscle, though they can be found within the orbicularis muscle in a small number of cases. While the labial arteries are never located superficial to the muscle, their depth varies, and they are found

closer to the free margin of the lip at the midline relative to the oral commissure.

Flap design

The surgeon should mark the vermillion border prior to infiltration of local anesthetic, as this margin often becomes distorted. Infraorbital or mental nerve blocks may be used to minimize some of this distortion. The flap is designed in a midline or paramedian location with a width that is approximately 50% the width of the defect. This helps to maintain the proportions of both lips, since closure of both the primary and secondary defects causes a similar reduction in width. The vertical height of the flap should be equal to the height of the defect. For extensive defects, an extended Abbe flap that includes skin beyond the mental crease has been described.^{21,22} Defects of the upper lip may be extended to replace the entire subunit and hide suture lines in the nasal sill or melolabial crease. A template is made and transferred to the desired location on the opposite lip. A medially or laterally based pedicle can be considered, but the side ipsilateral to the defect is often chosen to allow for a larger oral aperture postoperatively.

Flap elevation

Scoring incisions can be made at the vermillion border on both the flap and recipient defect to allow for precise re-approximation if skin markings become blurred. A full-thickness incision is made on the side opposite the pedicle. The labial artery is identified and ligated. The surgeon then moves to the pedicle side of the flap and transitions to blunt dissection at the orbicularis muscle to prevent transection of the labial artery. The pedicle should be approximately 1 cm in size to preserve venous outflow, which limits congestion and edema, as a wider or thicker pedicle can compress both the arterial supply and venous return. Hemostasis is achieved, and the donor site is closed in a layered fashion starting with oral mucosa. When suturing mucosa, the suture knots should face the oral cavity. Of note, a small opening should remain in the donor site at the origin of the pedicle to facilitate its rotation. The flap is rotated 180 degrees toward the defect.

Flap inset

The flap is inset and closed in a layered fashion identical to the donor site closure. The vermillion border should be carefully reapproximated. In addition, it is important to accurately align the orbicularis oris muscle to restore function.

Postoperative instructions

The Abbe flap serves as a connection between the upper and lower lips and prevents complete opening of the mouth. A liquid or soft diet is needed until pedicle division. Because narcotics can cause nausea and vomiting, antiemetics should be prescribed, or nonnarcotic analgesics should be considered. Many surgeons may also administer intraoperative or postoperative antibiotics. A bulky dressing is not needed for this repair and standard wound care with petrolatum ointment is recommended.

Second stage

The patient returns 3 weeks later and the pedicle is divided with a V-shaped incision. The resulting V-shaped defect on the recipient lip is closed primarily. The pedicle stump may be returned to the donor lip or excised and repaired with a linear closure. Pain is typically less after this stage than the first, and the patient may begin eating after surgery.

Technique pearls

Patients should be appropriately counseled regarding the anticipated difficulty with eating and speaking prior to pedicle division. Many patients are concerned about the edematous appearance of the flap, and they should be reassured that edema is normal for 4 to 6 months. No revisions should be attempted prior to 6 months to allow this swelling to resolve. Sensory and motor functions are affected during the procedure and it may require a year or more to regain complete neuromuscular function. Permanent dysfunction is possible, though rare, and patients should be appropriately counseled.

Misalignment of the vermilion is noticeable, and is more easily prevented than revised.

CUTLER–BEARD FLAP

The Cutler–Beard flap is a cutaneoconjunctival flap of the lower eyelid that is used to repair large, full-thickness defects of the upper eyelid. The donor site on the lower eyelid provides a perfect color and texture match, and the skin in this area is loose and able to stretch easily.

Flap design

The width of the defect is measured and a template is created. The template is transferred to the lower eyelid below the tarsal plate, and a rectangular flap is created.

Flap elevation and inset

A horizontal incision is made approximately 2 to 3 mm beneath the inferior tarsal plate and extended full thickness through the lower lid. Westcott scissors are useful to reach the desired depth on this thin skin. The flap is completed by two parallel, vertical incisions and transferred under the inferior tarsal plate. The lower lid palpebral conjunctiva is carefully dissected off the orbicularis muscle and attached to the levator aponeurosis and edge of the upper lid conjunctiva. The surgeon may consider using auricular cartilage or a free tarsal graft on the top of the conjunctiva to add support.²³ The skin and muscle of the lower eyelid flap are then advanced superiorly and sewn onto the upper lid in a layered fashion. The lower lid defect remains open.

Postoperative instructions

A dressing is applied for 48 hours. The patient's eyelid is sewn shut until division several weeks later, which can be very difficult for the patient, particularly if vision in the contralateral eye is poor.

Second stage

The patient returns 4 to 8 weeks later and the pedicle is divided. The pedicle recoils inferiorly and is sutured to the lower lid margin. The upper eyelid conjunctiva is advanced to the lid margin.

Therapeutic pearls

Lymphedema is a common problem in this area, and persists for many months. Ectropion can result from lower eyelid laxity, and a lid-tightening procedure may be warranted. Entropion of the upper eyelid can occur, allowing hair and skin to touch and irritate the cornea. Ensuring the new anterior lamella is firmly attached to the cartilage or free tarsal graft can help prevent this. Given the morbidity and potential complications of this repair, it should be reserved for large defects when other reconstructive options have been deemed unsuitable. A modified Cutler–Beard flap with earlier pedicle division has been described.²⁴ In this procedure, a free tarsal graft is harvested from the contralateral upper eyelid and sutured to the posterior lamella and levator aponeurosis. A skin-only flap is created on the lower lid, and is elevated and sutured in a manner similar to the traditional Cutler–Beard flap. The pedicle is divided at 2 weeks and returned to the lower eyelid. The authors describing this technique found no cases of necrosis or entropion, though one patient had ectropion (Fig. 14A–J).²⁴

(E) Flap passed under the tarsal plate. (F) Cartilage graft placed for structural support. (G) Flap sewn in place. (H) Flap survival at follow-up 10 weeks later. (I) Pedicle divided. (J) Postoperative appearance at 1 month.

HUGHES FLAP

The Hughes flap is traditionally used for large, full-thickness defects of the lower eyelid involving >50 % of the lid margin. It is a tarsoconjunctival flap

from the upper eyelid that reconstructs the posterior lamella. The anterior lamella is often repaired with a full-thickness skin graft or advancement flap.

Flap design

The width of the defect is measured to determine the width of tarsus required. If greater than 2 cm is needed, the tarsal graft can be expanded to include conjunctiva at its edges. The upper lid is everted and marked 3 to 4 mm back from the superior lid margin, as this amount of lid margin is required to prevent entropion.^{23,25}

Flap elevation

The tarsus is incised and dissected off the orbicularis muscle with Westcott scissors to its superior edge. Dissection also occurs in a plane between Muller's muscle and the conjunctiva up to the superior fornix to transfer conjunctiva in the flap with the tarsus. Vertical incisions are made at the medial and lateral edges of the tarsus to allow for flap movement.

Flap inset

The newly created flap is brought down to the lower eyelid and attached to the conjunctiva. The anterior lamella can be recreated with a full-thickness skin graft or with an advancement flap from the cheek.

Postoperative instructions

A patch is often placed for 1 week, and the patient's eye is sewn shut until the second stage of the procedure.

Second stage

The pedicle is divided typically 3 to 4 weeks later, with an incision made just above the lower lid margin. A modified Hughes flap with pedicle division at 1 week has been described with no cases of flap necrosis or

failure.²⁵ The pedicle recoils superiorly and the remaining flap is removed at the upper lid tarsal plate.

Therapeutic pearls

Upper lid retraction can occur in 19% to 32% of patients if dissection during flap elevation does not extend into the superior fornix or if Muller's muscle and the levator aponeurosis are transferred into the flap.²⁶ The patient will lack eyelashes on the lower lid, but this flap otherwise provides an acceptable cosmetic and functional outcome. Bipedicle tarsoconjunctival flaps have also been reported, and prevent visual obstruction.²⁷

CONCLUSIONS

Surgeons often face large, complex defects after the removal of a skin cancer. Areas such as the eye, nose, and ear are challenging to repair due to their intricate three-dimensional shape, and one must carefully consider form, function, and free margins when selecting an option for reconstruction. Interpolation flaps are an excellent option for these difficult defects in the right patient, and can reliably and safely be performed in the outpatient setting under local anesthesia.²⁸

CHAPTER 27 Z-Plasty

Jessica Lori Feig
Daniel B. Eisen

SUMMARY

- The Z-plasty is a powerful technique utilizing the transposition of triangular flaps to relieve tension, to lengthen, and to reorient scars parallel to relaxed skin tension lines.
- A 60-degree Z-plasty is considered optimal when considering skin laxity, size of the flaps needed for viability, risk of vascular compromise, location, and theoretical limitations.
- The Z-plasty may be used on its own for scar revision or repositioning, or as an adjunct to other flap closures to mitigate pivotal restraint.

Beginner Tips

- Z-plasty is useful for the functional improvement of contractures, web revision, or free-margin distortions
- Two equivalent triangular flaps synchronously interchange into the space previously occupied by the other. The result of the position swap is a 90-degree reorientation of the common arm of the Z.

Expert Tips

- Fundamental goals of the Z-plasty procedure include:
 - Realignment of a scar within relaxed skin tension lines (RSTLs), or parallel to them
 - Lengthening of a scar
 - Release of a contracture by scar lengthening
 - Dispersal of a scar for better camouflage

Don't Forget!

- In one study, survey respondents preferred a simpler and less complex linear scar over Z-plasty scars, suggesting that the purported benefit of breaking up long scars into smaller ones needs more study before it can be accepted.
- Although the surgeon has two choices for the placement of these lateral limbs, only one combination will allow for optimal cosmesis or reorientation of lines in the direction of, or parallel to, the RSTL.

Pitfalls and Cautions

- If a scar already lies along RSTL, a Z-plasty may result in reorientation of the central incision perpendicular to the RSTL—a less desirable outcome.
- Scars within 40 degrees of RSTLs may be better managed with simple excision rather than with Z-plasty.
- Necrosis is more common with angles less than 30 degrees and therefore such acute angles should be avoided if possible.

Patient Education Points

- While a Z-plasty does result in a longer scar line, patients may be reassured that the net result is generally a less cosmetically obvious scar.
- Other scar revision procedures may be needed after Z-plasty, and patients should be warned of this eventuality prior to surgical intervention.

Billing Pearls

- Z-plasty is billed using the adjacent tissue transfer (flap) code series, 140XX.
- These codes include a 90-day global period.
- If a Z-plasty is performed as part of a larger flap, only a single flap code should be used.

CHAPTER 27 Z-Plasty

INTRODUCTION

The Z-plasty is a standard technique utilizing the transposition of triangular flaps to relieve tension, lengthen, and reorient scars parallel to relaxed skin tension lines (RSTLs). This technique has been utilized for over a century with only slight modifications, relying on three incisions separated by angles of the surgeon's choosing. Though a variety of different angles can be used, 60 degrees is considered optimal when considering skin laxity, size of the flaps needed for viability, risk of vascular compromise, location, and theoretical limitations.

HISTORICAL PERSPECTIVES

Introduction of the Z-plasty dates back several centuries.¹ In the early 1800s, Fricke and Horner described single transposition flaps, the fundamental basic subunit of the Z-plasty. In his 1837 clinical report, Dr. William Horner illustrated its use for ectropion repair.² Later, Serre and Denonvilliers were invoking its use for facial reconstruction.^{3,4} In 1904, Berger exchanged triangular flaps of equal size and equal angles for axillary web contracture correction, performing the first double transposition Z-plasty 9 years before the term “Z-plasty” was used.⁵ In 1913, McCurdy published a paper entitled, *Z-plastic surgery: plastic operations to elongate cicatricial contractions of the neck, lips and eyelids and across joints*.⁶ Later, variations of the Z-plasty arose to include multiple Z-plasties, proposed by Morestin in 1914, for the treatment of retracting scars of the hand.⁷

Limberg expounded on the mathematical basis of the technique, delineating nuances previously ambiguous to many in his handbook for surgeons published in 1963.⁸ This work explained with two-dimensional models the movement of flaps and the reaction to their action in the adjacent tissue. Defining the geometric principles of the basic Z-plasty technique, he wrote: “Geometrical selection of symmetrical forms of convergent triangular flaps shows decrease in width and growth in length at the ends of the diagonals.”⁸ Its biomechanics was further refined by McGregor, who applied the law of cosines to the inherent foundation of the Z-plasty design which is utilized today.⁹

APPLICATIONS

Few comparative studies exist in the literature for Z-plasty versus other methods of repair. A retrospective review of a Japanese plastic surgery department’s cases of axillary scar contractures over the last 25 years showed that 31 axillary scar contractures were treated with Z-plasty, all of which showed no flap necrosis, though two cases of scar contracture recurrence were reported.¹⁰ Another prospective study of 82 patients undergoing partial selective fasciectomy for Dupuytren’s contractures compared the Z-plasty to two established models, and the incidence of flap necrosis with the Z-plasty was 7%.¹¹ In 2007, Tatlidede et al. studied resistance to tensile loads of various closures with 4–0 silk in murine models and concluded that Z-plasty was superior to linear incisions.¹² The breaking forces of the Z-plasty were roughly two times higher than that of the linear incisions 4 weeks after surgery, which may be explained by differences in contact surface area of the incision lines and decreased tensile forces which act on oblique lines of transposition flaps, as suggested by the authors.¹² Ertas et al. used murine models to study the effective elongation achieved by the Z-plasty or the subcutaneous pedicle rhomboid flap in inguinal skin and found that both techniques were effective in relieving tension over the inguinal areas and in lengthening tension lines, with the Z-plasty producing a greater than 200% gain in length.¹³

A retrospective study by Fader et al. reviewed the University of Michigan Mohs Database from 1998 to 2000 in an effort to identify cases where flap

transposition was used.¹⁴ Their analysis revealed that Z-plasty was used in 12 of 614 patients with cheek defects, all with good to excellent cosmetic and functional outcomes as rated by patient and surgeon.¹⁴ Of those, a double Z-plasty was performed in a subset of four cases. While no infection occurred, minor superficial tip necrosis occurred at one site.

One of the purported benefits of Z-plasty is that it takes a linear scar and breaks it up into smaller segments that, though longer in combined length than the original scar, are less aesthetically noticeable. This dogma was tested in a prospective national survey that assessed the public's aesthetic rating of computer-generated linear facial scars in three different locations in four individuals.¹⁵ Survey respondents significantly preferred the simpler and less complex linear scar over Z-plasty scars, suggesting that the purported benefit of breaking up long scars into smaller ones needs more study before it can be accepted. Thus, while Z-plasty is clearly useful for functional improvements of contractures, web revision, or free-margin distortions, as well as scar reorientation, its utility beyond these applications remains unproven.

The Z-plasty technique

The classic Z-plasty is a surgical method of scar repair which is defined by a Z-shaped incision. The method relies on the transposition of the two triangles created by the angles of the arms of the Z-incision. In other words, two equivalent triangular flaps synchronously interchange into the space previously occupied by the other (Fig. 27-1). The result of the position swap is a 90-degree reorientation of the common arm of the Z. Fundamental goals of the Z-plasty procedure include the realignment of a scar within RSTLs, or parallel to them; the lengthening of a scar; the release of a contracture by scar lengthening; and the dispersal of a scar for better camouflage.¹⁶

Figure 27-1. The classic Z-plasty. (A) The central limb of the original Z-plasty overlies the original scar. (B) After transposition of the triangular flaps created by the Z-plasty, the central limb is reoriented perpendicular to the original scar and parallel to the relaxed skin tension lines.

In its purest form, three incisions of equal length creating a Z, or its mirror image, are the integral steps in the execution of the technique. A central incision is made (in scar revision, this common limb overlies the original scar), and two adjoining limb incisions flank the central limb. It is important to note that although the surgeon has two choices for the placement of these lateral limbs, only one combination will allow for optimal cosmesis or reorientation of lines in the direction of, or parallel to, the RSTL (Fig. 27-2).¹⁷ Therefore, each incision's relationship to the RSTL is critical when planning Z-plasty to address scar orientation.

Figure 27-2. Z-plasty can reorient a scar 90 degrees. (A) A scar is oriented perpendicular to the right melolabial fold. (B) One choice for the Z-plasty is an incision line that lies over the original scar line and two adjacent vertical lines that serve as the limbs of the complete Z-plasty. (C) The other option for the Z-plasty is an incision line that overlaps the original scar and two horizontally placed incisions. (D) This figure represents the outcome of the transposition which takes place after the two triangular flaps in figure B exchange positions. The central limb now lies within the melolabial fold, now 90 degrees to its original position. Moreover, the two vertical incision lines fall within relaxed skin tension lines. This choice is favorable. (E) This figure represents the outcome of the transposition which takes place after the two triangular flaps in figure C exchange positions. Here, the horizontal incisions will not fall within the relaxed skin tension lines, essentially creating scars which will not hide within the natural contours of the facial lines. Note that both designs will reorient the original scar 90 degrees, to a position within the melolabial fold. However, one choice is clearly better than the other.

Another important factor in successful implementation of the Z-plasty is the angle created by the central and lateral limbs. Although angles from 30 to 90 degrees are possible, the 60-degree Z-plasty is the most common. As a general rule, the 60-degree Z-plasty should reorient the central scar by 90 degrees and yield a 75% increase in the length.

Classically, the Z-plasty consists of three equivalent incisions at 60-degree angles (Fig. 27-1). The central incision often overlaps the long axis of the scar, or alternatively the site of the defect if the scar is excised. After undermining the surrounding skin, the resultant triangular skin flaps are freed from the subcutaneous plane which lies below. The triangular flaps are then

exchanged so that the shared side of the triangles now lies against the skin of the lateral limb incisions and the resultant central limb is reoriented in a perpendicular fashion, ideally now parallel to RSTLs.

The Z-plasty procedure should not be used for every scar revision. If a scar already lies along RSTL, a Z-plasty may result in reorientation of the central incision perpendicular to the RSTL, typically a less desirable outcome. Similarly, scars within 40 degrees of RSTLs might be better managed with simple excision than with Z-plasty.¹⁸ Large Z-plasty approaches should generally be avoided given the substantial tension vectors that may exist across their common limbs; in such cases, multiple Z-plasty, as detailed below, would be preferable.

Z-plasty variants

Double-opposing Z-plasty includes two mirror image Z-plasty flaps placed immediately adjacent to each another (Fig. 27-3). After transposition of the triangular flaps, which naturally interdigitate with each other, there is a broadly based large flap with a preserved and intact vascular network. This application of the Z-plasty is primarily utilized in the areas of limited skin availability, laxity, or vascularity.¹⁹ As such, the technique is most useful in scar contractures, webs, or burns.

Figure 27-3. Double-opposing Z-plasty. (A) This modification consists of two mirror image Z-plasties placed immediately adjacent to one another. The *dotted line* represents the axis of reflection. Flap a and flap b swap positions and flaps c and d engage in a similar exchange. (B) The final result of the transposition. Since this application is primarily utilized in areas of limited skin availability, laxity, or vascularity, it is most useful in the treatment of scar contractures, webs, or burns.

The dancing man is a modification of the double- opposing Z-plasty technique (Fig. 27-4). Here, the Z-plasties share a common limb. First described by Mustardé, the dancing man has been primarily utilized in the epicanthal region²⁰ and later applied to the release of skin contractures.²¹

Figure 27-4. The dancing man. Mustardé's design shares components of the double-opposing Z-plasty. Note that the Z-plasties share a common limb.

The unequal triangle Z-plasty is another variation of the original Z-plasty technique (Fig. 27-5). Unequal triangular flaps are a result of a Z-shaped incision using nonparallel limbs and dissimilar angles between the limb incisions and the central incision. The half-Z is one example of this method, where one of the Z-plasty limbs is perpendicular to the central incision (Fig. 27-5C,D). The unequal angle approach is often utilized when there are different degrees of laxity in regional skin, such as the palpebral area or overlying scar tissue.

Figure 27-5. The unequal triangle Z-plasty. (A) Flaps are often designed to suit the area of reconstruction. Here, the flap angles vary. (B) The flaps swap positions, and the final placement is illustrated. (C) The half-Z-plasty is a modification of the unequal triangle Z-plasty whereby one of the two flaps is 90 degrees. (D) The flaps of the half-Z-plasty undergo transposition. Note that the unequal triangle Z-plasty is useful in areas where small amounts of tissue need to be moved with as little distortion as possible such as near the eyes or lips. This Z-plasty technique is particularly useful in areas where normal skin elasticity varies such as the eyebrows.

The unequal triangle Z-plasty has been adapted in innovative ways. Mutaft et al. designed the “reading man” procedure, a spinoff of the unequal triangle Z-plasty technique for the repair of circular defects of the skin (Fig. 27-6).²² The resultant incisions produce the silhouette of a man who is reading a book

held in his hand, and flap transposition results in effective closures for defects up to 14 cm in diameter.²² Consistent findings at mean follow-up of 15 months reveal durable skin coverage with fine scars in all patients.²²

Figure 27-6. The reading man. (A) A modification of the unequal Z-plasty utilizes flap transposition to repair circular defects. (B) The outcome of the triangular flap exchange. The reading man has been utilized in the repair of large circular defects (1.5–14 cm in diameter) on the face and trunk.

The four-flap Z-plasty modestly redesigns the basic Z-plasty to include two extra limbs coming off the end of the central incision, thereby bisecting the original angles (Fig. 27-7). Traditionally, there are two types of four-flap Z-plasty, the 120 and the 90 degrees, with each angle divided in half to create four flaps. One of the greatest advantages of this technique is the considerable decrease in tension and increase in length it provides through the construction and subsequent transposition of four flaps.²³ It provides gains of length of two 60-degree Z-plasties (150% increase, at 75% per Z-plasty) or two 45-degree Z-plasties (100% increase, at 50% per Z-plasty) performed in parallel.²⁴ Consequently, this technique is often utilized at scar sites of the first interdigital web space of the hand and anterior and lateral neck where contractures often restrict areas of otherwise normal flexion. The four-flap Z-plasty releases these severe scar contractures through the additional length gained.

Figure 27-7. Four-flap Z-plasty. (A) An illustration of the four-flap Z-plasty shows 90-degree angles bisected into 45 degrees. (B) After flap transposition, each flap interdigitates with one another. The four-flap Z-plasty is commonly utilized in the release of web-space contractures.

The four-flap Z-plasty uncovers an important relationship: an increase in the number of transposition flaps yields greater gain in length. This relationship is also applicable to multiple Z-plasties arranged in series (Fig. 27-8). At times, often in the case of long contractures, multiple small Z-plasty in series is superior to the use of one large Z-plasty because though the theoretical amount of lengthening in the longitudinal axis along the central limbs are equivalent when comparing both methods, the compound Z-plasty provides less transverse shortening, along the lateral limbs on the horizontal axis and less tension across the common limb.²⁵ Therefore, for long linear scars, the multiple Z-plasty is recommended. This procedure aims to divide the central limb into segments which ultimately distribute the tension across various smaller transverse diagonals. The redirection of these forces may improve the appearance of the scar.

Figure 27-8. Multiple Z-plasty. (A) With longer linear scars, significant tension is substantial at the diagonal and arms of the Z, oftentimes decreasing the value of the single Z-plasty. (B) In the multiple Z-plasty, a long linear scar is divided into smaller segments each of which undergo separate Z-plasty, distributing the tension across many smaller transverse diagonals.

Some drawbacks to multiple Z-plasty relate to the degree of tension on adjacent flaps from neighboring transposition flaps. This not only adds to a reduction in the theoretical gain in length, but also leads to flap distortion. Multiple Z-plasty may lead to a sawtooth pattern when applied to a web.²⁶

The traditional Z-plasty technique and associated variations predispose the scar to stereometric elongation, that is, a bulging effects or dog-ear (standing cone) formation, particularly when performing Z-plasty on flat surfaces.^{27,28} Though normal tensile forces and the elasticity of the skin routinely counter the bulging effect, the outcome is not always flawless, and inelastic skin is most vulnerable to bulging. To circumvent these issues, Roggendorf in 1983 introduced the planimetric Z-plasty which allows for elongation only within the skin plane.²⁸ To achieve this, a Z-plasty with 75-degree angles is created with limb incisions twice the length of the central limb (Fig. 27-9). This central incision is then extended in both directions to create an imaginary diagonal line between the end of the lateral limb incision and the central limb, measuring twice the length of the original limb incisions. The two triangular areas that are created are excised prior to flap transposition. Roggendorf calculated that the efficacy of planimetric Z-plasty,

measured as the fraction of skin elongation to scar elongation, exceeds that of the classic Z-plasty by 28%.²⁸ In practice, it is challenging to predict the elongation effects due to patient and site characteristic differences. Nevertheless, it is advantageous that some parts of a scar can be excised by execution of planimetric Z-plasty. This approach is useful in the treatment of irregular scars with mild contracture.

Figure 27-9. Planimetric Z-plasty. (A) 75-degree angles are utilized in this version of the Z-plasty. Limb incisions are twice the length of the central incision. Once the central incision is extended in both directions, two triangular areas are excised. (B) The effect of flap transposition. This technique is useful for correcting scars on flat surfaces and helps to avoid the elevations and depressions that can form with other types of Z-plasty, thereby creating smooth elongation of the skin along the scar axis.

Another Z-plasty variant is the spider procedure design. It converts a skin defect to an equilateral triangle with closure by five flaps harvested from the neighboring skin in a double-opposing Z-plasty manner (Fig. 27-10).²⁹

Figure 27-10. The spider procedure. (A) The illustration presents a triangular defect and incisions, which result in the formation of five flaps. Arrows signify the directions of the planned transpositions to repair the triangular defect. (B) The diagram is a representation of the final result of the spider procedure, after all flap transpositions take place. After converting skin defects to equilateral triangles, this technique can be utilized in the closure of defects in high-tension locations.

The Z-plasty aims to improve the appearance of the scar, relieve tension during wound closure, and correct scar contractures (Figs. 27-11 to 27-13). In the treatment of scars and contractures, the most appropriate design must be selected from the many options available to the dermatologic surgeon. It has been suggested that the greatest advantage of the Z-plasty is replacement

of an existing unattractive scar opposing RSTLs with a new scar which conforms to these lines,³⁰ though not all evidence supports this notion.¹⁵

Figure 27-11. Z-plasty utilization in web correction. (A) Postprocedure photo of a primary defect near the medial canthus. (B) The photo illustrates the late sequelae of scarring near canthal folds. Oftentimes, treated lesions near the medial canthi predispose to surgical webs. (C) Medial and lateral canthal webs can be corrected with Z-plasty. Superimposed “Z” represents the required incisions for surgical correction. Note that the central limb of the Z overlies the primary problematic tension band. (D) After the flaps undergo transposition, tension is relieved. (E) A photo of the web repair with Z-plasty as noted during his follow-up appointment.

(C) After the incisions are performed, triangular flap transposition occurs for proper execution of the Z-plasty technique. (D) Postprocedure photo representing the final result of the Z-plasty technique in the repair of a medial ectropion. Note the presence of a Frost suture for stabilization. (E) Photo of ectropion repair with Z-plasty as documented during patient's follow-up appointment.

Figure 27-13. Scar contracture repair and eyebrow asymmetry treated with Z-plasty. (A) Photograph of left malar eminence scar contracture in female patient. Also note patient's eyebrow asymmetry. (B) Mapping of a multiple Z-plasty across the right lateral forehead to correct brow asymmetry. (C) Immediate postoperative appearance. (D) The patient at a follow-up appointment. Note the absence of scar contractures at the operative site of the Z-plasty and correction of the brow asymmetry.

The evaluation and planning of the Z-plasty procedure is influenced by more than simple geometry.¹⁷ Outcome predictions are a combination of formulaic skin biomechanics and intuition. Though the principles of flap dynamics are a function of skin mobility and deformability under tension, differing skin extensibility, or laxity, impacts the end result. Clinical studies by Gibson and Kenedi showed lengthening ranged from one-third less to two-thirds more than expected from their geometric calculations.³¹ This large degree of variability points to the fact that geometry alone is not a predictive measure of outcomes. Other studies have demonstrated similar findings.^{32–34}

Complications

Though Z-plasty is a useful tool, complications do occur. The manipulated skin can be vulnerable to flap necrosis and hematoma formation, the former of which is common in Z-plasty with angles less than 30 degrees and with flap tips which necessitate frequent handling.^{17,35} Therefore, it is best to avoid the use of Z-plasty with such acute angles and minimize direct manipulation of triangular flap tips when possible.

CONCLUSIONS

Familiarity with the Z-plasty approach provides the surgeon with a useful tool to release contracted scars and reorient scars that are not located within RSTLs. Though breaking up a long scar into smaller, less noticeable segments has been espoused as a benefit of the Z-plasty, evidence that it accomplishes this purpose is anecdotal. The Z-plasty is an essential tool for the dermatologic surgeon when considering web and free-margin correction.

CHAPTER 28 Skin, Cartilage, and Composite Grafts

Melanie A. Clark
Christine Poblete-Lopez

SUMMARY

- With the exception of ear and large lower extremity defects, grafts are usually a second- or third-line option for surgical repairs, as primary closure, flap closure, and second intention healing may result in superior cosmesis.
- Cartilage grafts may be very helpful for recreating the ala and preventing notching as well as ensuring adequate valve function.

- Grafts may be used as solitary closures, as adjuncts to other repairs such as flaps, and as a rescue approach when a linear repair is under excessive tension.

Beginner Tips

- Widely undermine the FTSG recipient site to minimize the risk of a pincushion deformity.
- Meticulous suturing techniques to maximize contact of the skin graft with the wound bed should be employed.
- The antihelix is an excellent cartilage graft donor site with minimal cosmetic or functional penalty.

Expert Tips

- Grafts designed to cover Mohs defects can be harvested at a 45-degree angle to match the angle of the bevel used during the Mohs procedure.
- Composite grafts are ideal for small, deep wounds that involve a skin and cartilage defect, but should not be used on larger defects.

Don't Forget!

- Delayed skin grafting over areas of exposed bone or cartilage can be used to improve chances of graft survival.
- A graft with superficial necrosis is not necessarily doomed; careful wound care and watchful waiting can still result in a satisfactory final outcome.
- Shearing forces are the primary adversaries of graft success.

Pitfalls and Cautions

- Meticulous hemostasis must be performed in the wound bed prior to graft placement to ensure that hematoma does not interfere with the graft's contact with the nutrient-rich wound bed
- Failure to place fenestrations within an STSG can increase the chance of serosanguinous fluid pooling and graft necrosis.
- The use of an FTSG for a wound >5 cm or a wound with a tenuous blood supply is not recommended due to risk of graft necrosis.

Patient Education Points

- Even perfect graft selection and surgical technique cannot prevent graft failure in patients with heavy tobacco use.
- Lack of patience in awaiting graft maturity before the 3-month postoperative time point can result in unnecessary stress and scar refinement procedures. Regular follow-up and reassurance are key.

Billing Pearls

- Skin grafts are coded based on location, involved tissue, and size.
- STSGs are coded with the 15100 series; FTSGs with the 15200 series; cartilage grafts from the ear are coded as 21235; and composite grafts are coded as 15760.
- Donor site closure is included in the graft coding.
- If two separate graft types, or a graft and flap, are performed on the same day, they should both be coded, though they are subject to the multiple-procedure reduction rule.
- There is a 90-day global period associated with these codes.

CHAPTER 28 Skin, Cartilage, and Composite Grafts

INTRODUCTION

The use of skin grafts dates back to Hindu culture over 3000 years ago when the Tilemaker caste in India reported the successful use of skin grafts from the buttocks to repair defects of the nose, lip, and ear caused by mutilation as punishment for crimes such as adultery and theft.^{1,2} The first reports of successful full-thickness skin graft (FTSG) and split-thickness skin graft (STSG) use in the Western world did not appear in published works until the 19th century.¹

Although primary closure and local flaps are typically favored to reconstruct post-Mohs surgical defects for optimal color and texture match, skin grafts play an important role in dermatologic surgery. The practicing dermatologic surgeon should be skilled in the selection, harvesting, and placement of FTSGs, STSGs, cartilage grafts, and composite grafts. Skin grafts can be used for the reconstruction of a broad range of surgical defects of varying sizes, shapes, and depth across the entire cutaneous surface.

Classification

Skin grafts can be described as split thickness when they contain the entire epidermis and a portion of the dermis with few or no adnexal structures. FTSGs contain the entire epidermis and dermis as well as adnexal structures. Cartilage grafts, as the name implies, contain cartilage and are typically harvested from the ear in dermatologic surgery. Composite grafts contain the entire epidermis and dermis, as well as adnexal structures and cartilage.

Indications

Skin grafts are selected when repair with primary closure, flap repair, or healing by second intention are not viable options, or are deemed to be inferior options for the surgical patient. Skin graft repair is performed in almost 10% of Mohs reconstructions, and tends to follow a greater number of Mohs layers for tumor extirpation than the number of layers required when linear repair, local flaps, or granulation is selected.³ Skin graft repair may also be chosen in some patients over local flap repair when optimal cosmesis is not the primary goal of reconstruction or when patient preference dictates a simpler single-stage procedure over a multi-stage interpolation flap.

Pathophysiology

Skin, cartilage, and composite grafts are completely removed from their underlying supporting vascular structures and transplanted to a foreign wound bed where revascularization connecting the wound bed to the graft must successfully take place for graft survival. The metabolic requirements of skin grafts are directly related to their thickness; thus STSGs have a lower metabolic demand than FTSGs, which in turn have a lower metabolic demand than composite grafts.

The stages of skin graft healing can be divided into three stages: imbibition, inosculation, and neovascularization. There may be significant overlap between these stages. Imbibition is the first stage of graft survival that occurs during the first 24 to 48 hours of graft placement.⁴ During this phase, the graft is ischemic, and graft survival is dependent on local plasma exudate of the recipient wound bed which enters the graft by passive diffusion and increases the graft weight by up to 40%.⁵ Fibrin forms beneath the graft, keeping the graft in contact with the wound bed. The second stage of graft survival, inosculation, begins approximately 48 to 72 hours after graft placement, and is characterized by the growth of new capillaries from the recipient bed that anastomose with the vasculature of the donor graft.⁶ Because the graft recipient site must be well-vascularized prior to graft placement for this step to occur, graft recipient sites with exposed bone or cartilage where periosteum or perichondrium have been stripped often

benefit from delayed grafting to allow granulation tissue to form in the wound bed prior to graft placement.⁷ The final stage of graft survival, neovascularization, occurs in conjunction with inosculation, with completion 7 to 10 days after graft placement. Neovascularization describes the achievement of capillary ingrowth and anastomosis between the wound bed and graft with re-establishment of lymphatic flow.⁶⁻⁸ Postsurgical reinnervation of skin grafts has been demonstrated on a molecular level.⁹ However, clinically significant reinnervation of grafts is modest, with less than a third of patients with skin grafts on the face able to detect light touch 2 years after graft placement.¹⁰

PREOPERATIVE CONSULTATION AND CONSIDERATIONS

Adequate preoperative consultation is paramount for patient education and postoperative satisfaction. Realistic expectations must be set regarding tissue color and texture match, and all patients should be counseled that even the most ideally matched skin graft will leave scar lines. Patients should also be counseled that the appearance of skin grafts generally improves with time, and that the cosmesis of grafts and scar lines can be improved with chemical peels, dermabrasion, and ablative or nonablative laser therapies in the postoperative period.

Intrinsic and extrinsic factors that will affect graft survival should be discussed, particularly those that are amenable to behavioral modification. Patients with peripheral vascular disease should be counseled that their graft survival may be inferior compared to those in healthy patients, particularly if graft placement is on the distal extremities. Smoking has been shown to impede wound healing and increase the rate of graft and flap necrosis.^{11,12} Studies suggest that the short-term vasoconstrictive effects of nicotine abate within 48 hours of nicotine withdrawal.^{13,14} Although no consistent guidelines regarding smoking cessation after graft placement exist, smokers may be counseled on the benefits of smoking cessation at least 1 week preceding graft placement and for 1 week postoperatively, with the ideal period being as long as the patient is able to abstain, as adequate blood flow

to the delicate anastomosing capillary network of the wound bed and graft in the weeks following surgery is vital.

All nonprescription medications and supplements that can increase bleeding risk in the postoperative period should be discontinued with the following recommendations:¹⁵

- Ephedra: 24 hours
- Gingko: 36 hours
- Alcohol: 2 days
- Ibuprofen: 2 to 5 days
- Ginseng, garlic, vitamin E: 1 week

Aspirin should not be discontinued if a physician has prescribed it. If aspirin has not been prescribed by a physician, use should cease at least 1 to 2 weeks preoperatively.⁷ Although the bleeding risk in patients on warfarin and other anticoagulants is higher than that of those not on anticoagulation, the risk remains low.¹⁶ Prescription anticoagulants, including warfarin, antiplatelet agents, direct thrombin inhibitors, and direct factor Xa inhibitors should not be discontinued preoperatively to avoid potentially dangerous thrombotic events.

Complications

The most common complications during the postoperative course of graft healing are hematoma, seroma, necrosis, and infection. Hematoma formation can be avoided by meticulous hemostasis and avoidance of all nonessential anticoagulants. The graft and wound bed should be in complete contact, and shearing forces should be minimized in order to optimize the chances of graft survival and minimize the risk of hematoma and seroma. This can be achieved by skillful placement of sutures that are placed first through the graft, then through a section of the wound bed, and finally back through the skin edge before the suture knot is tied. Basting sutures through the center of the graft are commonly used to improve contact of the skin graft with the wound bed and allow for optimal imbibition, inosculation, and neovascularization. Skin graft fenestrations may be utilized, particularly in large grafts, to allow for drainage of blood and serous fluid that would

otherwise compromise contact of the graft with the wound bed. Bolster dressings made of plain or petrolatum-impregnated gauze, dental rolls, or cotton balls either tied on or kept in place with adhesive material can also be employed to maximize graft contact with the wound bed (Fig. 28-1). Although bolster dressings are commonly used, there is no evidence supporting superior graft survival with their use.^{17,18}

Figure 28-1. A bolster dressing is placed to maximize contact of the FTSG with the wound bed.

If adequate blood supply cannot be established between the graft and the wound bed, full or partial graft necrosis may occur. The risk of graft necrosis can be mitigated by the same tactics used to minimize seroma and hematoma formation, in addition to smoking cessation. Graft necrosis is often heralded by the formation of a black eschar. Should this occur, gentle debridement should be performed. Often, a necrotic-appearing graft manifests only partial-thickness necrosis, and can still heal with excellent cosmesis once the superficial slough is eliminated and re-epithelialization takes place with the aid of daily gentle cleansing and application of petrolatum ointment (Fig. 28-2). Given their increased metabolic demand, composite and FTSGs are at higher risk for necrosis than STSGs.

Figure 28-2. (A) A partially necrosed FTSG. (B) The partially necrosed FTSG is healing well with conservative wound care. (C) The once-necrotic FTSG has healed with an atrophic scar. The patient incidentally has an additional FTSG on the nasal ala after a subsequent Mohs surgery that is healing well.

The signs of wound infection include warmth, erythema, edema, purulent drainage, and a putrid odor. Wound infection has the potential to compromise skin graft healing. If a wound infection is suspected, a bacterial culture

should be obtained and oral antibiotics directed at the causative organism should be started.

Contraindications

If a surgical wound bed does not have an adequate blood supply, such as in an area of bone or cartilage devoid of periosteum or perichondrium, a skin graft is unlikely to survive. To improve the chances of graft survival and optimize cosmesis, delayed grafting may be considered to allow the wound bed to revascularize and form granulation tissue that will serve as a rich nutrient bed for the incipient graft.^{19,20} A hinge flap can also be utilized, where a flap of muscle or fat adjacent to the defect is incised with its vascular pedicle intact and inset over the surgical defect to allow for immediate graft placement (for a full discussion of hinge flaps, see [Chapter 43](#)).^{21,22}

FULL-THICKNESS SKIN GRAFTS

FTSGs are indicated when a surgical defect is unable to be repaired by primary or flap closure techniques and when second intention healing is likely to result in a poor cosmetic or functional outcome. FTSGs are commonly utilized to repair defects on the nasal tip, nasal ala, ear, medial canthus, eyelids, digits, and scalp ([Fig. 28-3](#)).²³ FTSGs are thicker and thus more metabolically demanding than STSGs, though FTSGs are able to restore full skin contour and offer a better cosmetic appearance than STSGs. FTSGs are able to cover defects up to 4 to 5 cm in diameter before the risk of graft necrosis due to overwhelming metabolic demand becomes significant, whereas STSGs are able to cover much larger defects.⁷

A

B

C

D

Figure 28-3. (A) A patient with a large nasal tip defect who declined paramedian forehead flap repair is repaired with an FTSG from the neck. Graft survival and acceptable cosmesis are apparent at suture removal, 6-week follow-up, and long-term follow-up. (B) A patient with a defect on the nasal ala is repaired with an FTSG harvested from the conchal bowl. (C) A defect on the helical rim is repaired with an FTSG harvested from the preauricular skin. Graft survival at suture removal 1 week postoperatively and excellent long-term cosmesis are observed. (D) A patient with a defect extending from the right medial canthus onto the right nasal sidewall is repaired with an FTSG from the mandible. Postoperative ecchymosis is present at suture removal. Excellent long-term cosmesis is achieved. (E) A defect on the posterior auricle is repaired with an FTSG from the postauricular neck. Basting sutures are placed to optimize contact of the FTSG with the wound bed. (F) A defect of the triangular fossa of the ear is repaired with an FTSG from the neck. Normal color changes are observed at suture removal 1 week postoperatively. At 6-week follow-up, almost complete healing is achieved. At long-term follow-up, the graft is healed with a slightly atrophic scar.

Graft selection

The donor site should be selected carefully from an area of skin with similar color, texture, thickness, background photodamage, degree of sebaceousness, and degree of hair density as the skin surrounding the surgical defect. The graft donor site should be selected from an area where harvesting of the graft will not cause significant functional or cosmetic compromise, and where the donor site scar can be easily concealed. When an optimal match is not possible between the skin appearance of the donor and recipient site, poor cosmetic outcome is more likely to occur.

FTSGs are commonly used on concavities and convexities of the upper two-thirds of the ear, where they can provide excellent topographic and contour restoration.²⁴ Although a combination of a cartilage graft with an FTSG may be necessary for defects where a significant portion of the helical rim cartilage has been removed, FTSGs can frequently be used alone for defects of the remainder of the ear when helical rim cartilage is intact. The preauricular sulcus, postauricular sulcus, and postauricular neck tend to have similar color and baseline photodamage as the ear, making them ideal donor sites for defects of the helix, anterior ear, and posterior ear.

While local flaps are often the preferred reconstructive option for defects on the nose for optimal cosmesis, FTSGs provide a straightforward repair and closure option and an acceptable cosmetic outcome for many patients. For defects on the nasal tip and ala, the conchal bowl is a common FTSG donor site owing to its similar color and sebaceousness. Furthermore, providing the perichondrium is left intact, wounds in the conchal bowl are able to granulate well and heal by second intent with minimal cosmetic penalty.

Defects of the nose that are too large for a conchal bowl graft are often repaired with FTSGs from the preauricular sulcus or postauricular neck where the degree of photodamage is similar to the nose and scars can be easily concealed. For defects of the lower eyelid, FTSGs from redundant skin of the upper eyelid, harvested using a blepharoplasty-type technique, can be utilized with favorable tissue match. Other common FTSG donor sites used for larger defects of the face, scalp, and extremities are the clavicle and inner upper arm (Table 28-1).

Table 28-1. Common FTSG Donor and Recipient Locations

Defect Location	FTSG Donor Site
Nose	Conchal bowl, preauricular cheek, postauricular sulcus, postauricular neck
Ear	Postauricular sulcus, postauricular neck, preauricular cheek
Lower eyelid	Upper eyelid
Medial canthus	Upper eyelid, postauricular sulcus, preauricular cheek
Scalp	Postauricular sulcus, postauricular neck, supraclavicular, upper inner arm

Technique

The donor site is first scrubbed with antiseptic and anesthetized. The surgical defect is then measured in both horizontal and vertical dimensions and a graft template is drawn with a surgical marking pen on the donor site. If the graft donor site is to be closed primarily, the standing cones to be removed can be drawn at the same time. It is recommended to oversize the harvested graft 10% to 20% to account for tissue contraction and ensure a final graft that is sufficiently sized for the surgical defect (Fig. 28-4).

B

C

D

Figure 28-4. Step-by-step FTSG repair. (A) A surgical defect on the left nasal ala is present after Mohs micrographic surgery for a basal cell carcinoma. (B) The defect is measured and a template is drawn on the neck, which has been selected as the FTSG donor site. (C) The donor site skin is excised in a standard fashion. (D) Iris scissors are used to de-fat the FTSG until shiny white dermis is visible across the graft. (E) The surgical defect is undermined to minimize postoperative pincushion deformity. (F). The FTSG is placed on the recipient wound bed. (G) The graft is sutured in place with anchoring sutures. (H) The FTSG is trimmed to perfectly fit the surgical defect. (I) Remaining sutures are placed (not pictured) and a bolster dressing is placed as desired. (J) The FTSG donor site is repaired with a standard layered closure.

A no. 15 Bard-Parker scalpel is used to excise the donor graft tissue with or without the planned standing cones. If the surgical defect to be repaired is a defect from Mohs micrographic surgery, beveled edges are usually present in the wound bed. If the beveled edges are maintained, the graft should be harvested at a 45-degree angle for optimal fit.²⁵ If the graft is excised at the standard 90-degree angle, the wound edges of the Mohs surgical defect should be trimmed to reflect right angles, so the graft may optimally fit in place.

The donor site is excised down to the level of the adipose tissue, with the exception of the conchal bowl graft, which is excised to the level of full dermal thickness down to cartilage, leaving perichondrium intact. Immediately after excision, the graft is placed in a small sterile basin containing sterile saline, and hemostasis is achieved at the graft donor site.

The graft is then placed epidermis down with subcutaneous fat exposed over the gloved nondominant hand or over a gauze pad in the nondominant hand. The harvested graft is traditionally de-fatted with curved iris scissors until white shiny dermis is exposed over the entire skin graft. It should be noted that although de-fatting is a standard practice in dermatologic surgery to minimize the risk of graft necrosis, retaining 1 to 5 mm of subcutaneous fat on FTSGs may be considered with pleasing aesthetic results, particularly for the repair of deeper defects on the lower one-third of the nose.²⁶

The skin edges of the recipient wound bed are then undermined to minimize potential postoperative pincushion deformity. The graft is accurately positioned over the wound bed, and simple interrupted sutures are placed at opposite ends of the graft to secure it in place. Meticulous hemostasis must be performed in the wound bed prior to graft placement to ensure that hematoma does not interfere with the graft's contact with the nutrient-rich wound bed. Depending on graft location, 6-0 polypropylene, 5-0 polypropylene, or 5-0 fast-absorbing gut sutures are favorable sutures to secure the graft.

Iris scissors are used to trim the graft to the exact size of the wound bed, and additional simple interrupted sutures are placed to secure the graft. The suture is first placed through the graft and then through the donor skin to maximize accurate approximation and minimize trauma to and displacement of the graft. Sutures should be placed down to the level of the reticular dermis of the graft and donor site skin to anchor the graft to the wound bed

for optimal graft survival and to reduce the risk of depressed scar lines.²⁷ Central basting sutures may also be placed to maximize graft contact with the wound bed. For larger grafts, a running suture may also be used once several anchoring sutures are placed evenly around the periphery of the graft.

The donor site is then repaired in a standard fashion using a layered closure technique. If a conchal bowl graft is harvested, the graft donor site is left to heal by second intention. If a delayed FTSG is performed, the graft is placed over the granulating wound bed 2 to 4 weeks after surgery. Before graft placement, the wound bed is first curetted down to a healthy base, and the skin edges are freshened by excising 1- to 2-mm margin of the wound edge.¹⁹

Burow's grafts

A Burow's graft is most commonly used when a wound cannot be completely closed primarily or when closing a wound primarily would distort a free anatomic margin such as the alar rim, lip, or eyelid (Fig. 28-5). The Burow's graft allows for the use of skin of a similar texture and color. This graft can also be used for defects that span two cosmetic units, allowing the first unit to be closed primarily and the second to be grafted with skin of optimal visual match.^{27,28}

Figure 28-5. A BCC is observed on the left alar crease (A) and a surgical defect is created after tumor extirpation with Mohs micrographic surgery (B). A Burow's graft is used to close the central portion of the wound in order to avoid alar distortion that would have resulted if the wound was closed primarily (C). Excellent cosmesis is achieved at suture removal (D).

To perform a Burow's graft, the standing cone removed from the partial primary closure is used to repair the residual defect rather than being discarded. Graft placement technique is the same as that used for the conventional FTSG. In hair-bearing areas such as the mustache, beard, and scalp, Burow's grafts can be particularly useful to restore normal hair growth within the surgical defect, and this graft may be conceptualized as a localized hair transplant procedure.

Cosmetic considerations

Graft contraction is common, and FTSGs may contract on average up to 30%. Grafts on the nose and periorbital area are most prone to contraction.²⁹ Pincushion deformity and hypertrophic scars may also occur at graft sites. Although color match of FTSGs with their recipient sites usually improves

over time, hyper- or hypopigmentation may be persistent, particularly if the FTSG is harvested from an area with suboptimal color match. Hypertrophic scars and pincushion deformities can be improved with intralesional steroid injection, while contour irregularity and color match can be improved with dermabrasion (Fig. 28-6), ablative lasers, medium-depth chemical peels, or a combination of these therapies.

Figure 28-6. Initial suboptimal postoperative contour and color match of this patient's FTSG (A) are improved after dermabrasion (B).

SPLIT-THICKNESS SKIN GRAFTS

STSGs are composed of epidermis and a portion of dermis, but do not usually contain hair or adnexal structures. STSGs generally range in thickness between 0.125 and 0.75 mm, and can be classified based on the amount of dermis in the graft as thin (0.125 to 0.275 mm), medium (0.275 to 0.4 mm), or thick (0.4 to 0.75 mm).²³

STSGs have lower metabolic requirements than FTSGs or composite grafts, and can be used to cover defects >5 cm. They are more likely to survive in wound beds with a suboptimal vascular supply, and are typically used to cover large wounds that would be slow to granulate and cannot be repaired by local flap or FTSG closure (Fig. 28-7). Moreover, in locations at high risk for tumor recurrence, STSGs offer the benefit of providing a thin “window” covering that can allow for straightforward monitoring of tumor recurrence under the graft.²³ STSGs can also be fenestrated, either manually or by a meshing device, to increase their surface area. STSGs are aesthetically inferior to FTSGs and local flaps, and do not usually offer ideal color or texture match with the surrounding skin. STSGs contract more than

FTSGs, and once healed usually appear as atrophic white or hypopigmented patches without visible adnexal structures.

A

B

Figure 28-7. (A) A large surgical defect of the lower leg is repaired with an STSG. The healed final wound is pictured. (B) A large surgical defect after Mohs micrographic surgery for a basal cell carcinoma of the forehead is repaired with an STSG harvested from the thigh. This patient had minimal surrounding skin laxity secondary to multiple previous surgeries for nonmelanoma skin cancers as a result of radiation therapy for acne during adolescence. The graft is observed to be healing well at suture removal.

Graft selection

The donor site of an STSG heals by second intention. Donor-site scars usually appear as a hypopigmented patch, although in darker skin types these can heal as a hyperpigmented patch. STSG donor-site scars are typically >5 cm, and thus STSGs should be harvested from areas that can be easily covered by clothing such as the abdomen, lower back, hips, buttocks, thighs, and proximal arms. The patient should be counseled that pain at the donor site is usually worse than that experienced at the recipient site.

Technique

STSGs can be harvested with a no. 10 blade, Weck blade, or electric dermatome. The donor site is scrubbed with antiseptic and then anesthetized. The defect is measured, and a corresponding template is drawn on the donor site with surgical marking pen. If the STSG will be meshed with a meshing device to cover a very large defect, the graft can be undersized by 25% to 35%.⁷ If the STSG will not be meshed, the graft should be oversized by 10% to 20% to account for tissue contraction and ensure adequate wound coverage. Although STSGs contract to a greater extent than FTSGs, they can still be oversized to the same degree as FTSGs. STSGs may be uniformly fenestrated to allow for the outflow of blood and serous drainage, thus increasing their potential area of wound coverage and offsetting the extent of contraction observed compared to FTSGs.

If a freehand STSG is planned, a no. 10 blade is used to superficially score the area of skin to be excised while the skin is held taut. The blade is then placed nearly parallel to the skin, and starting at the scored edge the scalpel is used to create a surgical plane through the dermis while the graft is gently lifted from the wound edge with toothed forceps.

If the Weck blade, a razor-like knife, is used, the skin is held taut, and a sawing motion is employed with the blade placed almost parallel to the skin with forward and downward pressure applied, similar to a shave biopsy. If an electric dermatome is used, desired graft thickness is first adjusted on the dermatome. The operating surgeon then applies downward and forward pressure with the advancing dermatome while the skin is held taut and the skin graft is delivered from the dermatome with toothed forceps. Mineral oil can be applied to the surface of the skin to minimize friction and improve the dermatome blade's ability to glide smoothly and uniformly across the skin surface.

If a meshing device is used, the desired expansion grid is selected and inserted into the device. The graft is then placed flat into the meshing device and advanced through with a lever. The harvested graft is transferred to a basin containing sterile saline. After careful hemostasis is achieved at the recipient site, the STSG is placed on the wound, trimmed with iris scissors to fit the defect, and sutured into place in a similar manner as with FTSGs. STSGs are typically quite large, and although simple interrupted sutures can be placed around the entire periphery of the graft site, suturing efficiency can be optimized by first positioning a number of interrupted anchoring sutures evenly around the edge of the graft and then placing a running suture around the entire graft perimeter. If the STSG was not meshed, a no. 10 or no. 15 blade can be used to create uniform linear fenestrations within the STSG. This allows serosanguinous fluid from the wound bed to drain into the dressing rather than pool under the graft where it will interfere with the graft's ability to contact the wound bed. The donor site should be dressed with a moist occlusive dressing consisting of petrolatum, an absorbent layer, and surgical tape. The pinpoint bleeding present at the donor site will abate with a pressure dressing alone, and additional hemostasis with aluminum chloride or electrocautery is usually not required.

FREE CARTILAGE GRAFTS

Cartilage grafts are used to maintain the protuberant structures of the nose and ears. Cartilage grafts are composed of cartilage with adherent perichondrium, and can be grafted alone or attached to the overlying skin as a composite graft. Cartilage grafted alone allows for more flexibility in donor

site selection. The cartilage support structure can be harvested separately from the skin that is selected to cover the defect from a local flap or skin graft. Cartilage grafts are commonly used in the repair of nasal defects, especially of the nasal ala to prevent alar notching or collapse, and to preserve function of the nasal valve. Cartilage grafts are also commonly used on the helical rim when helical cartilage is removed during tumor extirpation to preserve the natural curve of the helix and prevent aesthetically displeasing notching of the ear. They provide an invaluable tool to prevent poor functional and cosmetic outcomes that result from the forces of contraction during wound healing at anatomic free margins (Fig. 28-8).

A

B

Figure 28-8. (A) A full-thickness defect of the nasal ala is repaired with a free cartilage graft from the conchal bowl to recreate the natural curvature of the ala. The cartilage graft is harvested with a postauricular approach. An FTSG is harvested from the postauricular skin to cover the surgical defect and cartilage graft. Alar form and function are preserved at suture removal and excellent cosmesis is achieved at 6-week follow-up. The cartilage graft donor site heals well without aesthetic penalty. (B) A full-thickness defect of the nasal ala is repaired with a free cartilage graft from the antihelix to preserve alar contour. The overlying FTSG is harvested from the skin of the antihelix. Favorable contour and color match are achieved at long-term follow-up.

Graft selection

Antihelical and conchal bowl cartilages are both commonly used for repairs in dermatologic surgery. Conchal bowl cartilage is typically used when a larger piece of cartilage is required for repair of the nasal ala, columella, septal cartilage, or the crura of the lower nasal cartilage.³⁰ Although crural cartilage is an option for cartilage and soft tissue reconstruction, cartilage of the antihelix is usually sufficient in dermatologic surgery.

The cartilage of the antihelix is more elastic, less brittle, and has a greater innate curve than that of the concha, which generally makes it a more favorable option when a cartilage graft is required along an anatomic structure with natural curvature such as the helical rim or nasal ala.³¹ The antihelix is also easily accessible, and once the cartilage strip is harvested, the tension-free donor site can be closed primarily leaving a resulting scar that is almost imperceptible. Although typically cartilage grafts are covered with either a local flap or an FTSG, a cartilage alar batten graft alone may be sufficient in select patients for alar reconstruction with acceptable functional and aesthetic outcomes.³²

Technique

The cartilage graft donor site is first scrubbed with antiseptic and then anesthetized. The skin can be incised without a skin excision if a small cartilage graft is to be taken. A single incision with skin hook retraction on the wound edges can allow for adequate dissection of the overlying skin and visualization of the cartilage to be harvested. If a larger cartilage graft is planned, an ellipse of skin over the cartilage graft can first be removed to help visualize the underlying cartilage. The surgical defect is measured, and the cartilage graft is oversized by 10% to 15% relative to the size of the

cartilage strut required for structural support in order to have adequate length to tuck the cartilage graft edges into the recipient site.⁷

The cartilage graft is harvested using a no. 15 blade and is incised through the anterior perichondrium, through the cartilage, and then through the posterior perichondrium, with care taken not to incise through the postauricular skin. The graft is gently lifted using forceps, with care taken not to traumatize the delicate tissue. The cartilage graft can also be separated from the surrounding cartilage using iris or Castroviejo scissors. Thorough hemostasis is achieved at the recipient site. Small pockets are then created under the edges of the recipient skin using blunt dissection with surgical scissors or hemostats to create a space where the graft will be placed to interlock with the wound bed.³³

The graft is inserted into the wound bed, and a 5-0 absorbable lassoing suture is placed around the cartilage graft and through the wound bed to anchor the graft in place. If it is not possible to create pockets in the recipient site for the insertion of the edges of the cartilage graft, the edges of the graft can be sutured to the periphery of the wound bed with absorbable sutures. The freestanding cartilage graft is most often covered with an FTSG, transposition flap, or interpolation flap. The cartilage graft may also be left to heal by second intention with or without delayed grafting. The patient should be counseled that the cartilage graft donor site is likely to be more painful than the recipient site postoperatively due to chondritis of the donor auricular cartilage. Although no formal recommendations exist for antibiotic prophylaxis after cartilage graft placement, many suggest a fluoroquinolone antibiotic to minimize the risk of infection and subsequent graft failure.

COMPOSITE GRAFTS

Composite grafts contain cartilage, perichondrium, and overlying skin, and are thus the most metabolically demanding grafts. The metabolic demands of composite grafts limit their use to small, deep defects where cartilage and skin replacement is required, such as the marginal tissue of the alar rim (Fig. 28-9).

Figure 28-9. A full-thickness defect of the nasal ala is repaired with a composite graft from the crus of the helix.

Graft selection

When a partial or full-thickness alar rim or soft triangle defect ≤ 1.5 cm in diameter is present, a composite graft composed of skin and cartilage from the crus of the helix is a viable repair option.^{34,35}

Technique

The recipient wound bed edges are trimmed for a smooth semicircular contour. The donor site is scrubbed with antiseptic and anesthetized. A foil template from suture material provides a suitable three-dimensional material to be drawn and trimmed to the exact size and shape of the surgical defect, erring on the side of oversizing rather than undersizing to account for graft

contraction. As with free cartilage grafts, the cartilage portion of the graft may be oversized to fit into grooves created at the periphery of the recipient wound bed. Using the foil template, the donor site on the crus of the ear is traced with a surgical marking pen. A no. 15 scalpel is used to excise the composite graft containing skin, perichondrium, and cartilage, and the graft is briefly placed in a basin of sterile saline. Hemostasis is achieved at the graft recipient site, and the graft is inset into the surgical defect. If the cartilage is oversized for deliberate interlocking into the wound bed, pockets on each side of the recipient are first created with blunt dissection in the same manner as with the freestanding cartilage graft. To achieve a perfect fit, any excess skin or cartilage tissue from the composite graft that does not fit into the defect is trimmed with iris scissors. If a full-thickness alar defect is present, simple interrupted sutures are first placed on the mucosal side of the graft to secure it into place. Then, simple interrupted sutures are placed around the periphery of the skin graft on the epidermal surface. The graft donor site is left to heal by second intention or is repaired with a transposition flap from the immediate postauricular skin.³⁵ As with free cartilage grafts, patients may be treated with fluoroquinolone antibiotics after composite graft repair.

POSTOPERATIVE CARE

Patient education regarding the expected postoperative course and proper postoperative care is imperative for optimal surgical outcomes. The patient should be counseled about normal physiologic color changes seen in a graft during the immediate postoperative period. The graft will initially appear blanched and white. As imbibition begins to take place in the days following surgery, the graft will become edematous and violaceous. As inosculation and neovascularization are initiated and established around 1 week postoperatively, the graft will appear more pink in color. In the months following surgery, the edema of the graft will dissipate, and the color of the graft will return to the initial color of the donor skin.

The most important pearl in the immediate postoperative care of skin grafts is the avoidance of any shearing forces which will disrupt the inosculation and neovascularization of the immature graft and significantly increase the risk of necrosis. The use of bolster dressings has been

advocated to decrease shearing forces and it is some dermatologic surgeons' preference to routinely employ these. However, the use of bolster dressings has not been definitively demonstrated to increase the chances of graft survival.^{17,18,26} Table 28-2 is a list of pearls regarding the use of grafts and Table 28-3 is a list of pitfalls.

Table 28-2. Pearls

When harvesting from the preauricular region, take care not to transplant terminal hair follicles to a nonhair-bearing area.
Widely undermine the FTSG recipient site to minimize the risk of a pincushion deformity.
For skin grafts extending over the alar crease, a bolster suture can be placed in a linear fashion where the alar crease should naturally occur to improve nasal contour.
Delayed skin grafting over areas of exposed bone or cartilage can be used to improve chances of graft survival.
Grafts designed to cover Mohs defects can be harvested at a 45-degree angle to match the angle of the bevel used during the Mohs procedure.
Meticulous suturing techniques to maximize contact of the skin graft with the wound bed should be employed.
A graft with superficial necrosis is not necessarily doomed; careful wound care and watchful waiting can still result in a satisfactory final outcome.
The antihelix is an excellent cartilage graft donor site with minimal cosmetic or functional penalty.
Composite grafts are ideal for small, deep wounds that involve a skin and cartilage defect.

Table 28-3. Pitfalls

Shearing forces are the primary adversaries of graft success.

Failure to place fenestrations within an STSG can increase the chance of serosanguinous fluid pooling and graft necrosis.

Inadequate hemostasis may result in hematoma and decrease the rate of graft survival.

The use of an FTSG for a wound >5 cm or a wound with a tenuous blood supply is not recommended due to risk of graft necrosis.

Even perfect graft selection and surgical technique cannot prevent graft failure in patients with heavy tobacco use.

Lack of careful graft selection for ideal color match is likely to result in suboptimal aesthetic outcomes.

A graft that is undersized is much more difficult to alter for ideal fit than a graft that is oversized.

Wound infection increases the likelihood of graft failure and graft contraction. Prompt assessment and appropriate treatment of wound infections are crucial.

Lack of patience in awaiting graft maturity before the 3-month postoperative time point can result in unnecessary stress and scar refinement procedures. Regular follow-up and reassurance are key.

If a bolster is not placed, the pressure bandage placed postoperatively should be left for 24 to 48 hours. After removal, the patient is instructed to gently wash the area with a mild soap and water once or twice daily. The graft is then covered with petrolatum ointment and a sterile bandage. This is repeated until suture removal, which is performed at 5 to 7 days for grafts on the face, 10 to 12 days for grafts on the scalp, and 12 to 14 days for grafts on the trunk and extremities. If a dry tie-on bolster dressing is placed, most dermatologic surgeons advocate keeping the surgical site dry for 1 week postoperatively until the bolster is removed. If petrolatum-soaked gauze for the bolster dressing is utilized, the patient is generally recommended to gently wash around the bolster dressing daily and apply additional

petrolatum ointment on and around the dressing to preserve the moist environment of the surgical site.

If an eschar is present at suture removal, this does not necessarily indicate complete graft necrosis. It is not uncommon to observe superficial slough that can be gently debrided. Grafts that are thicker or on poorly vascularized wound beds are more prone to this outcome. With continued daily cleansing and petrolatum ointment application, many of these grafts will re-epithelialize with a satisfactory aesthetic result. If complete necrosis does occur, the necrotic graft should be gently debrided, and the wound allowed to heal by second intention before any additional revision surgeries or procedures are planned.

The appearance of grafts tends to significantly improve in the 3 to 4 months following surgery. Most patients will require close follow-up and reassurance during the postoperative period. It is recommended to wait at least 3 months before performing scar revision or refinement procedures.

CONCLUSIONS

Skin grafts are most often utilized when primary closure, flap repair, and second intention healing are not feasible or inappropriate for the repair of a surgical defect. Although the cosmesis of skin graft closures can be inferior to that of wounds closed primarily or by flap closure, skin grafts provide a straightforward one-step procedure for anatomic areas with minimal skin laxity. Excellent aesthetic results and functional outcomes are possible with appropriate graft selection, meticulous surgical technique, and patient compliance. A thorough knowledge of the indications, selection, technique, complications, and postoperative care of FTSGs, STSGs, cartilage grafts, and composite grafts is essential for the practicing dermatologic surgeon.

CHAPTER 29 Mohs Micrographic Surgery

Ramona Behshad

SUMMARY

- Utilizing horizontal sections permits the full peripheral and deep margin to be assessed by the Mohs surgeon.
- Mohs surgeons act as both surgeon and pathologist.
- Mohs has the highest cure rate for nonmelanoma skin cancers, and is appropriate for most nonmelanoma skin cancers of the head and neck.
- Appropriate use criteria were jointly developed by the AAD, ACMS, ASDS, and ASMS to delineate which tumors are appropriately treated with this technique.

Beginner Tips

- Meticulous attention to detail is required for all steps of Mohs surgery.
- An experienced technician is vital in the preparation of high-quality slides for evaluation.
- Overlap between stages is critical to success.
- Technical errors impacting slide quality are the most common cause of recurrence after Mohs surgery.

Expert Tips

- Beware of aggressive curettage.
- Excessive facing of the block is associated with both false-positive and false-negative results.
- Patients with a history of CLL or organ transplant have a significantly higher rate of prominent inflammatory foci, increasing the challenge of slide interpretation.

Don't Forget!

- When removing cartilage, including some noncartilaginous tissue at one edge will prevent the cartilage from floating off during processing.
- Keep in mind the risk of cerebral air emboli with exposed calvarium.
- Always overlap areas of positive tumor.

Pitfalls and Cautions

- Sectioning tissue may be associated with an increased risk of error; therefore, if appropriate, tumors may be embedded as a single unit.
- Fat should be frozen to a lower temperature to encourage appropriate cutting; this can be accomplished by using a cryogen.

Patient Education Points

- Mohs provides the highest cure rates of any technique for the treatment of skin cancer.
- Patients should come prepared for a full day at the office and bring a book, electronic device, and snacks if desired.

- For patients that are squeamish or anxious, Mohs may not represent the best option for treatment, or perioperative anxiolytics could be considered.

Billing Pearls

- Coding for Mohs is relatively straightforward, with the 17311–2 series and 17313–4 series used for tumors of the head/neck/hands/feet/genitalia and all other areas, respectively.
- The add-on codes (17312 or 17314) may never be used in isolation.
- If Mohs surgery is continued on a subsequent day, coding begins anew.
- Mohs surgery codes may never be utilized if the same physician does not act as surgeon and pathologist.
- Biopsies or frozen sections performed on the day of surgery should be billed with the appropriate modifier. Remember to document the need for the biopsy and frozen section interpretation and outline that it is distinct from the Mohs procedure.

CHAPTER 29 Mohs Micrographic Surgery

INTRODUCTION

Mohs micrographic surgery (MMS) is a specialized surgical technique that achieves the highest cure rates of any skin cancer treatment, making it the treatment of choice for most skin cancers on the head and neck as well as for recurrent or histologically aggressive lesions. It differs from other techniques in that microscopic margin examination occurs using an intraoperative stepwise approach, thereby eliminating the need to estimate tumor extent. Unlike standard tissue processing, Mohs surgery uses horizontal frozen sections that capture 100% of the peripheral and deep surgical margin in one plane. Residual tumor, if present, is mapped and excised selectively until the entire tumor is removed.

Incorporating meticulous tumor mapping into the removal process requires the surgeon to act in two distinct capacities: as surgeon and pathologist. This further lowers the potential for human error in a situation where tissue orientation is of critical importance. It is well suited for contiguous tumors, most commonly basal cell carcinoma (BCC) and squamous cell carcinoma (SCC), although it is being used more frequently for rarer cutaneous tumors and for melanocytic malignancies (see [Chapter 31](#)).

Many studies have demonstrated the efficacy of MMS for the treatment of skin cancer.¹⁻⁴ MMS has a 5-year cure rate of 98% to 99% for previously untreated BCC^{1,3,4} and 94% to 97% for SCC.^{1,2,5} For recurrent BCC, the 5-year recurrence rate remained lower after treatment with MMS (5.6%) than

after surgical excision (17.4%), electrodessication and curettage (40%), or radiation therapy (9.8%).³

Since Mohs surgery allows removal of the cancer with minimal waste and damage to normal surrounding skin, long-term functional and cosmetic results may be optimized. Still, with each procedural step, there is the opportunity for small errors by the Mohs surgeon and lab technician that can be additive, and therefore, strict attention to detail is of critical importance.

INDICATIONS

Mohs surgery is not necessary for all skin cancers. The indications for Mohs surgery have been recently defined based on pathologic tumor characteristics, tumor size, clinical tumor characteristics, and certain host characteristics.⁶ Scoring is assigned as appropriate (7 to 9), uncertain (4 to 6), or inappropriate (1 to 3) for Mohs surgery based on factors detailed below and in [Table 29-1](#).

Table 29-1. Scoring for Mohs Surgery

	Appropriate	Uncertain	Inappropriate
Area H			
BCC	Primary or recurrent: aggressive, nodular, superficial		
SCC	Primary or recurrent: aggressive, nonaggressive, verrucous, KA-type SCC, SCC in situ/Bowen		Primary or recurrent: AK with focal SCC in situ
Area M			
BCC	Primary or recurrent: aggressive, nodular, superficial (IC) Primary: superficial >0.6 cm	Primary: superficial <0.5 cm	
SCC	Primary or recurrent: aggressive, nonaggressive, KA-type SCC, SCC in situ/Bowen		Primary or recurrent: AK with focal SCC in situ
Area L			
BCC	Recurrent: aggressive, nodular Primary: aggressive >0.6 cm, nodular >2 cm (>1.1 cm in IC)	Primary: aggressive <0.5 cm, nodular 1.1–2.0 cm (0.6–1 cm in IC), superficial (IC) >1.1 cm	Recurrent: superficial Primary: nodular <1 cm (<0.5 cm in IC), superficial of any size (<1 cm in IC)
SCC	Primary or recurrent: aggressive Recurrent: KA-type SCC, nonaggressive Primary >2 cm Nonaggressive (IC), SCC in situ/Bowen Primary >1.1 cm Nonaggressive (IC), KA-type SCC, SCC in situ/Bowen (IC), KA-type SCC (IC) >0.6 cm	Recurrent: SCC in situ/Bowen Primary 1.1–2.0 cm Nonaggressive, SCC in situ/Bowen Primary <1 cm Nonaggressive (IC) Primary 0.6–1 cm SCC in situ/Bowen (IC) Primary <0.5 cm KA-type SCC (IC)	Primary or recurrent: AK with focal SCC in situ Primary <1 cm Nonaggressive, KA-type SCC, SCC in situ/Bowen Primary <0.5 cm SCC in situ/Bowen (IC)

Listed indications are for both healthy and IC patients, and tumors of any size unless otherwise specified. Nonaggressive SCC indicates SCCs without aggressive features, <2 cm depth without other defining features, Clark level <3.

AK, actinic keratosis; BCC, basal cell carcinoma; KA, keratoacanthoma; IC immunocompromised; SCC, squamous cell carcinoma.

Area H: Mask area of the face (central face, eyelids, eyebrows, nose, lips, chin, ear, periauricular skin, temple), genitalia, hands, feet, nail units, ankles, and nipple/areola.

Area M: Cheeks, forehead, scalp, neck, jawline, pretibial surface.

Area L: Trunk and extremities (excluding pretibial legs, hands, feet nail units, and ankles).

Data from Ad Hoc Task Force¹, Connolly SM, Baker DR, et al: AAD/ACMS/ASDSA/ASMS 2012 appropriate use criteria for Mohs micrographic surgery: a report of the American Academy of Dermatology, American College of Mohs Surgery, American Society for Dermatologic Surgery Association, and the American Society for Mohs Surgery, *J Am Acad Dermatol*. 2012 Oct;67(4):531–550.

Location

Tumor location can be subdivided into three areas: high risk, medium risk, and low risk (Fig. 29-1). High-risk areas (H) include the “mask areas” of the face (eyelids, eyebrows, nose, lips, chin, ear, periauricular skin, and temples), genitalia, hands, feet, nail units, ankles, and nipples or areola. Medium-risk areas (M) include the head and neck areas (cheeks, forehead, scalp, neck, and jawline) and pretibial surface. Low-risk areas (L) include the trunk and extremities, excluding the areas included in areas H and M. Under the appropriate-use criteria, all SCC and BCC (except primary actinic keratosis with focal SCC in situ) are appropriately treated by Mohs if located in the H area. All skin cancers in the M area are considered appropriate, except for small superficial BCCs equal to or less than 5 mm in size and primary actinic keratoses with focal SCC in situ. MMS is typically reserved for larger, recurrent, or more aggressive tumors on L areas.

Figure 29-1. Tumor location can be subdivided into three areas: high-risk (**green**), medium-risk (**purple**), and low-risk (**orange**) areas. High-risk areas (H) include the “mask areas” of the face (eyelids, eyebrows, nose, lips, chin, ear, periauricular skin, and temples), genitalia, hands, feet, nail units, ankles, and nipples or areola. Medium-risk areas (M) include the head and neck areas (cheeks,

forehead, scalp, neck, and jawline) and pretibial surface. Low-risk areas (L) include the trunk and extremities, excluding the areas included in areas H and M.

Patient characteristics

Certain patients are at a greater risk for aggressive and recurrent tumors. Tumors in immunocompromised patients (HIV, organ transplantation, hematologic malignancy, or pharmacologic immunosuppression) have double the risk of metastatic disease compared with immunocompetent patients (13% vs. 5%).⁷ Patients with chronic lymphocytic leukemia also have higher rates of recurrence when compared with immunocompetent controls,⁸ and patients with genetic syndromes that make them more susceptible to skin cancers, such as xeroderma pigmentosum, basal cell nevus syndrome, and Lynch syndrome, are more likely to have aggressive tumors. These patients are all appropriate candidates for Mohs surgery even when tumor characteristics demonstrate lower-risk lesions.

Tumor characteristics

The preoperative biopsy should be reviewed for signs of aggressive histologic features, as such BCCs and SCCs are more likely to locally recur and metastasize. Morpheaform/fibrosing/sclerosing, infiltrating, metatypical/keratotic, and micronodular BCCs contain small nests of malignant cells and have a high propensity for recurrence.^{1,9} Sclerosing, basosquamous, poorly differentiated or undifferentiated, infiltrating, keratoacanthoma (central facial), clear cell, sarcomatoid, Breslow depth 2 mm or more, Clark level 4 or greater, pagetoid, single cell, lymphoepithelial, and small cell tumors similarly have an increased risk of recurrence and metastasis.^{7,10,11}

According to the appropriate-use criteria, any aggressive histologic feature for SCC makes it appropriate for MMS, regardless of all other characteristics. This guideline is similar for BCCs, with the exception of aggressive BCCs on location L that measure <5 mm in diameter. For all subtypes of BCC and SCC, perivascular and perineural involvement are indications for MMS. The presence of significant pain or paresthesia should alert the physician to the possibility of perineural invasion,¹² as this finding

is not always seen on initial biopsy due to sampling error. MMS is also appropriate for all tumors occurring within radiated skin, traumatic scars, areas of osteomyelitis, patients with genetic syndromes, and areas of chronic inflammation. Recurrence of a previously treated BCC or SCC is also a strong indication for using MMS.^{10,13}

PREOPERATIVE EVALUATION FOR MOHS MICROGRAPHIC SURGERY

The initial consultation forms the basis for all future interactions between the physician and the patient. The indications and alternatives to Mohs surgery, including standard excision or no treatment, must be discussed with the patient so that he or she may make an informed decision to proceed. As a relatively low-risk procedure, Mohs surgery can be safely performed in elderly patients with stable comorbid conditions.¹⁴

Once MMS has been deemed appropriate for a given tumor and patient, a history and focused physical examination should be performed. When obtaining the patient's past medical history, several medical and psychological issues are taken into consideration. These include allergies, medications (including anticoagulants and immunosuppressants), previous infections and hospitalizations, artificial implants, and genetic cancer syndromes. Discussion with the patient about cessation of tobacco use during the perioperative period should also occur. Cigarette smokers should be advised to decrease smoking to the greatest degree possible for 1 week before and 1 week after surgery to lessen the risk of poor wound healing.

Hemostasis

The presence of any implanted cardiac pacemakers and defibrillators should be noted, and an appropriate method of electrosurgery selected (see [Chapter 16](#)). For patients with pacemakers and implantable cardioverter defibrillators (ICDs), it may be safest to utilize electrocoagulation with bipolar forceps or a hand-held heat cautery device.^{15,16} When using standard monopolar electrosurgical devices, frequently practiced precautions include applying short bursts of energy (<5 seconds), using minimal power, and

avoiding use of electrosurgery around the implanted device.¹⁷ Epinephrine, which is commonly added to local anesthetics, should be avoided in epinephrine-sensitive patients.

Anticoagulants

Patients taking purely elective prophylactic anticoagulants and herbal supplements can be counseled to stop 1 to 2 weeks prior to surgery. Patients should not drink alcohol 24 hours prior to the procedure or 48 hours after the procedure to reduce the risk of bleeding. In patients taking medically necessary anticoagulants, however, the risk associated with postoperative bleeding is significantly lower than the risk of thromboembolic events that may occur if this anticoagulation is ceased.¹⁸ Therefore, most dermatologic surgeons allow patients to continue anticoagulants and antiplatelet medications in the perioperative period. In patients taking coumadin, an INR may be reviewed to ensure it is within the therapeutic window (and preferably three or less).

Prophylactic medications

Indications for antibiotic prophylaxis should be reviewed and prescribed for certain patients at risk for infective endocarditis, hematogenous joint infections, and/or surgical site infections. While Mohs surgery rarely falls into any of the qualifying categories for hematogenous joint or heart valve infections, prophylactic antibiotics are recommended when the surgical site is considered high risk for surgical infection. Sites and locations at high risk for surgical infection include the lower extremities, groin, wedge resection of the lip or ear, skin flaps on the nose, skin grafts, or areas of extensive inflammatory skin disease.¹⁹ For most procedures, a first-generation cephalosporin or dicloxacillin is adequate for wound infection prophylaxis (Table 29-2). Antivirals may also be considered if surgery will occur on anatomical sites of prior HSV outbreaks, such as the cutaneous or vermilion lip. Antianxiety medications can be prescribed, but cannot be taken until the patient has consented to the procedure.

Table 29-2. Prophylactic Medications for Mohs Surgery

Site	Antibiotic	Dose
Skin	Cephalexin	2 g PO
	Dicloxacillin	2 g PO
	Clindamycin ^a	600 mg PO
	Azithromycin/clarithromycin ^a	500 mg PO
Oral lesions and Mucosa	Amoxicillin	2 g PO
	Clindamycin ^a	600 mg PO
	Azithromycin/clarithromycin ^a	500 mg PO

All doses are given 30–60 minutes preoperatively as a single dose, although an extended course of antibiotic treatment can be considered.

^aAlternative medication for penicillin-allergic patients.

Data from Wright TI, Baddour LM, Berbari EF, et al. Antibiotic prophylaxis in dermatologic surgery: advisory statement 2008, *J Am Acad Dermatol*. 2008 Sep;59(3):464–473.

Physical examination

The physical examination is focused on identifying the tumor location, which should be documented prior to surgery and confirmed with the patient. Confirming the biopsy site is a prerequisite to proceeding with Mohs surgery, although this can be difficult in patients with severe actinic damage, multiple scars, rosacea, and many seborrheic or actinic keratoses. Photographs, diagrams, tangential lighting, Wood's lamp, and magnification are helpful,²⁰ as patients presenting for dermatologic surgery have been shown to be incorrect 16.6% to 31.4% of the time when attempting to identify their surgical site.²¹ If these measures are unavailable or unsuccessful, a protocol should be in place. One published protocol involves both physician and patient participation in biopsy-site identification at consultation. If the biopsy site was not identifiable, then further consultation was undertaken with the patient's referring provider and/or family. Frozen biopsies were employed if necessary to identify tumor sites on the day the patient presented for surgery. If the biopsy site still could not be identified, then frozen biopsy specimens were sent for permanent sections and the patient was observed at 3-month

intervals. Over a 6-year period, there were no cases of wrong-site surgery in 7983 MMSs performed; surgery was, however, occasionally deferred because the correct biopsy site could not be identified.²²

On the other end of the spectrum, patients with extremely large or deeply invasive tumors, especially with motor nerve findings or lymphadenopathy, may require a multidisciplinary approach and preoperative imaging or consultation. Ophthalmology, otolaryngology, radiology, oncology, surgical oncology, neurosurgery, and plastic surgery may all at times be consulted by the Mohs surgeon in the perioperative period.

TECHNIQUE

The fundamental technique was pioneered by Frederic Mohs in the 1930s, and his landmark article on 440 patients treated with chemosurgery was published in 1941.²³ At that time, Mohs used zinc chloride paste for in vivo fixation prior to surgical removal. Dr. Mohs applied zinc chloride paste to the cancerous skin to fix the tissue prior to excision. The following day, the tissue was excised and examined under the microscope. The process was repeated daily until the tumor margins were clear.

The original in vivo chemosurgical approach transitioned to the fresh frozen tissue technique beginning in 1953, an innovation pioneered by Dr. Mohs for eyelid cancers to prevent ocular damage by the zinc chloride paste. Subsequently, the technique was popularized and described in detail by Tromovich and Stegman in 1974.²⁴ The fresh frozen technique obviated the need for escharotic zinc chloride paste, allowed complete tumor clearance in 1 day and immediate surgical reconstruction.

The Mohs procedure is considered a *clean* procedure rather than a *sterile* procedure. Once the biopsy site is identified with confidence, and patient consent is obtained, the area is typically prepped with chlorhexidine or Betadine and then draped. Local anesthesia is first infiltrated. Lidocaine 1% to 2% with epinephrine 1:100,000 is used most commonly, although nerve blocks and long-lasting anesthetic such as bupivacaine may be helpful to prolong anesthesia (see [Chapter 12](#)).

With Mohs surgery, the tumor is removed in a saucer-shaped section and divided into pieces for processing ([Fig. 29-2](#)). Evaluation of all excised margins reveals skin cancer present at one edge. The area is subsequently

mapped and excised on layer II. With the Mohs method, no tumor is missed. In contrast, bread-loafing of the elliptical excision specimen for histologic examination could miss tumor extending to the margin because only a small portion of the margin is examined.

Figure 29-2. With Mohs surgery, the tumor is removed in a saucer-shaped section and divided into pieces for processing. Evaluation of all excised margins reveals skin cancer present at one edge. The area is subsequently mapped and excised on layer II. With the Mohs method of tissue processing, no tumor is missed. In contrast, bread-loafing of the elliptical excision specimen for histologic examination could potentially miss tumor extending to the margin since only a small portion of the margin is examined.

Appropriate instruments, organization, and setup are essential for optimizing outcomes (Fig. 29-3). The fresh tissue technique of MMS has been simplified into debulking the tumor followed by excising and orienting; sectioning and inking; flattening, embedding, and freezing; cutting and staining; and mapping the tissue. It takes great skill to take a Mohs layer that can be processed perfectly by the lab, and Mohs surgeons should be aware of the technical challenges inherent in each step of specimen processing. The success of the procedure is tied to the precise application of each step of the

technique and the expertise of the individuals performing them. Technical errors impact slide quality, and represent the most common cause of local recurrence after MMS.²⁵

Figure 29-3. Standard instruments for Mohs surgery. Clockwise from *top left* corner: cotton-tipped applicators, blade remover, dental rolls, curved hemostat, forcep, supercut scissors, scalpel with 15 blade, curette, electrocautery device, gloves overlying towels for draping, towel clamps, gauze, and a ruler.

Debulking

Many surgeons curette the lesion until visually normal skin is reached to help identify the tumor margins.^{26,27} To perform curettage, a curette is scraped over the tumor in different directions with moderate pressure, producing fragments of friable tumor that can be wiped away to reveal a clean wound base or to produce a vertically oriented slide of tumor pathology when a previous biopsy is unavailable or has not been done (Fig. 29-4). Curettage is helpful in debulking friable tumor prior to MMS, but it does not reliably delineate the entire extent of a tumor.^{27,28} Infection, crusting, hyperkeratosis, background seborrheic dermatitis, and actinic keratoses may exaggerate the tumor size, resulting in an overly large debulking layer.

Figure 29-4. Curettage prior to taking of first Mohs layer to debulk the tumor and clinically assess the gross tumor margins.

Since most MMS occurs after a diagnostic biopsy, there is frequently an area of eschar overlying the cancer site. Since it is of no clinical value and can interfere with the production of high-quality slides, the eschar should be removed by the surgeon or technician prior to processing the tissue.

Aggressive curettage is not advocated. Curettage may cause shearing forces on the remaining, adjacent epidermis that will be included in the Mohs layer, which may lead to epidermal separation that will appear as clefting at the dermal–epidermal junction or as epidermal loss. In addition, the technician may interpret torn epidermis as a purposeful nick, leading to inaccurate sectioning. In severely photodamaged skin, this can also result in overhanging pieces of epidermis at the edges that can lead to false positives if this free epidermis is embedded near the margin (Fig. 29-5). Floaters are also more common after curettage,²⁹ so care must be taken to wipe the debulked tissue prior to excising the layer (Fig. 29-6).

Figure 29-5. An artifact of aggressive curettage with overhanging epidermis implanted into the margin.

Figure 29-6. The curetted tumor is wiped away.

Excising tissue for optimal sectioning and orientation

The steps in Mohs excision are illustrated in [Figure 29-7](#). The Mohs surgeon must decide where to designate 12 o'clock on the excised specimen. Some practices always orient tissue toward an anatomic structure such as the vertex scalp or the ear lobule, while others orient 12 o'clock superiorly, medially, and/or posteriorly. The method is not as important as consistency. Thus, the Mohs surgeon always has a general idea of tissue orientation, even when the reference nick is not easily identifiable on the patient. Once this has been determined, the tumor is excised with a narrow clinical margin, including the deep plane, in a disk shape ([Fig. 29-7](#)). The margin varies from one to several millimeters depending on the size, location, and histology of the tumor. Before the skin is fully excised, several incisions (nicks) are made in the Mohs layer and in the adjacent skin for orientation, usually at 12-, 3-, 6-, and 9-o'clock positions although individual cases may require alterations ([Fig. 29-7](#)). The skin edges are beveled 30 to 45 degrees to allow for en face sectioning of the deep and peripheral margins simultaneously, with the exception of thin tissue such as eyelid and mucosa where little to no bevel is required ([Fig. 29-7](#)). After the tissue is completely removed, it is placed on a piece of gauze, filter paper, or a card ([Fig. 29-7H](#)). A map of the specimen is drawn, indicating the locations of the nicks that orient the tissue on the patient ([Fig. 29-8](#)). When specimens contain cartilage, bone, or subcutaneous tissue without any skin edge, this should be indicated on the map. Pressure and/or electrosurgery is used for hemostasis, and a dressing is applied to the surgical wound. The patient then waits for the tissue to be processed, which usually takes 30 to 60 minutes.

Figure 29-7. (A–C) Pie-shaped excision of the skin cancer with the scalpel blade at a 45-degree angle. (D–E) Hash marks are placed to orient the tissue. The specimen is cut with 12 o'clock as the superior orientation. The tissue is removed as one piece. The specimen should be cut from all edges

toward the center and not from one edge through to the other side. (H) The tissue is placed on filter paper for orientation to the patient and the card. In this case, the patient label indicates 12 o'clock.

Figure 29-8. (A) The tissue is taken to the lab accompanied by the patient requisition. A comparable drawing is made of the tissue noting the marking hashes that orient the tissue on the patient. Stage one specimen with reference nicks at 12, 3, 6, and 9 o'clock. A *double circle* represents the areas that epidermis is included. A *single circle* or *line* represents a nonepithelial, surgically cut edge on the Mohs map. Others may represent this differently, although a standard annotation for epithelial edge is necessary. (B) A case number (in this case B-241 is assigned). (C) Here, by convention, the tissue is oriented on the filter paper so that 12 o'clock is toward the patient label.

The excised tissue specimen is carefully transferred to the lab, maintaining proper anatomic orientation. A dot or patient label in a designated corner of the transfer medium may be used to designate 12 o'clock. The tissue is logged, usually with the patient's information, such as name, site, and a Mohs case number. The technician should scan for reference marks that approximate the accompanying map. Any discrepancies must be resolved with the Mohs surgeon prior to processing the tissue.

The specimen should be cut from the lateral epidermal edges toward the center by using separate incisions with the blade, and not by using a single

incision from one edge continuously through to the other side. This ensures a uniform bevel and a uniform base.

When removing a recurrent skin cancer, the scar should ideally be removed to a plane deeper than the previous surgery, and the peripheral margin should be cut wider than the scar, although local anatomy may alter the depth of tissue taken. Clinical judgment will determine whether the entire scar, or only a portion of the scar, needs to be excised.

When excising cartilage, including some noncartilaginous tissue at one edge will help the technician prevent the cartilage from floating off the slides during processing.

When excising deep layers for fat or muscle, the surgeon should ideally take 4- to 5-mm-thick specimens to allow adequate tissue for processing and to prevent visible holes in the tissue after processing. Novice surgeons may wish to paint the entire base of the Mohs defect with a nonvital dye prior to taking a deep section; ensuring that no dyed tissue remains after taking the layer guarantees that the entire deep margin was removed.

Always assess whether cutaneous or sensory nerves are at risk, and take necessary precautionary measures. These include injection to exaggeratingly tumesce tissue prior to excision, provide upward traction, and of course obtaining appropriate informed consent explaining the risk of nerve injury.

Sectioning and inking

Some tumors may be sectioned into two or more pieces prior to processing; however, analysis of a single specimen with four evenly placed marks of different colors provides clear direction when correlating microscopic findings with their location on the patient. The single-section method was described by Randle et al.³⁰ and minimizes the time needed for slide preparation and slide interpretation while also reducing the opportunity for error.³¹

The main factors determining when specimen subdivision is necessary are the size of microscope slides and the freezing and embedding technologies available to the technician. Convex and concave specimens, thick specimens, and specimens containing cartilage or bone usually required sectioning to be flattened into a single plane. Once appropriate sectioning has been decided, the hash marks are exaggerated, and the tissue is blotted to remove excess

water (Fig. 29-9). Dyes are applied to the nicks on the excised tissue and documented on the map that was drawn at the time of excision (Fig. 29-10). Some Mohs surgeons perform the inking themselves, while other Mohs surgeon delegate this task to their technician. Analysis of the specimen with nicks and colors provides clear direction when correlating microscopic findings with their location on the patient's defect. Inking is most helpful when the ink is placed along a significant portion of the surgical margin rather than just as an orienting dot at the specimen pole. In this situation, missing ink indicates that a margin is not fully evaluable. Most Mohs surgeons use red, blue, black, and possibly one or two other colors for this purpose. They are represented on the Mohs map with symbols for orientation purposes.

Figure 29-9. (A) The tissue is blotted to remove excess water. (B) The tissue was scored with hash marks by the Mohs surgeon during tissue removal. These small marks are enhanced by the technician to facilitate flattening the surgical margins into one plane. Along with reinforcing the existing marks, sometimes the tissue will dictate more relaxing cuts to be able to lay the entire specimen flat. When this cannot be accomplished by this technique, the tissue will be divided into sections to assure that the tissue sits on one plane, albeit in pieces.

Figure 29-10. (A) Commercially available dye system with applicators are placed in a stable holder. Once the tissue has been satisfactorily relaxed, ink is applied to the hash marks on the tissue to assist the Mohs surgeon in orientation if more stages are needed. (B) A cotton-tipped applicator is used to mark the tissue with tissue dye, which remains on the tissue through histochemical staining. When applying different colored inks to nearby tissue edges, it is good to approach the edge from the side being marked to prevent ink contamination and bleeding to unintended edges. (C) Specimen orientation, shape, reference mark location, and inking pattern are depicted on the map. In this example, XX is yellow, = is red, is green, and the four vertical lines represent blue. These symbols are used so that black and white copies can still be interpreted.

Cutting tissue into more than one section introduces a higher change of mislabeling specimens or for the Mohs surgeon to incorrectly map positive margins on the incorrect section. More sections also increase the risk of false-positive and false-negative margins.³¹

If too much ink is used, ink may inadvertently run over and confuse the margins. This may also occur if the specimen is too wet, thus emphasizing the need to blot the tissue prior to marking (Fig. 29-11). Poor-quality ink may be difficult to read and could be washed off during tissue preparation.

Figure 29-11. (A,B) The inked, relaxed tissue is placed on a labeled slide, deep margin down. Using forceps, the edges of the tissue are teased down flat on the slide. (C) Many times freeze spray is needed to help hold the tissue to the slide in a flat configuration. Flattening is important so that the epidermis, dermis, and subcutaneous fat lie in the same plane.

Tissue flattening

Since the specimen will be embedded horizontally for sectioning, the tissue must be flattened. For specimens that are beveled at an angle less than 45 degrees, or come from anatomic sites characterized by a thick dermis, the technician may place additional relaxing incisions in the specimen to facilitate the flattening of the section so that the plane of sectioning for the undersurface of the specimen is in the same plane as the epidermal margin. These incisions should be superficial enough to allow the tissue to flatten, but should not extend deep enough to cut the marginal surface of the specimen. Overly deep relaxing incisions may disrupt the orientation and the continuity of the margin and can introduce floaters by forcing tissue at the surface down to the base, producing a false-positive margin.

If there is inadequate relaxation of the tissue, peripheral margins may not be teased down effectively, which results in missing epidermis on the slides. In areas with thin skin, such as the eyelid, the skin may fold easily before embedding, resulting in slides that are cut tangentially and are therefore difficult to interpret.

Embedding and freezing

Once flattened, the specimen is frozen while in this level configuration and supported in a block of embedding medium, such as optimal cutting temperature (OCT) medium or a similar compound. The embedding medium binds tissue to the chuck and surrounds and supports the tissue during the cryosectioning phase. This prevents loss of tissue during processing, known colloquially as *chunking out*. The most commonly used methods to embed are the reverse slide mount method, embedding wells, and the cryo-embedder system.

The steps in the reverse slide method are as follows:

1. The tissue is mounted on a glass slide, deep side down. Full tissue contact between the tissue and the surface of the slide is assured by gently pressing the periphery of the specimen into contact with the slide and pressing out any air bubbles. This can be assisted with freeze spray to prevent lifting of the epidermis ([Fig. 29-11](#)).
2. Subsequently, a mounting medium such as OCT is applied. The tissue, embedding medium, and slide are then frozen to approximately to -15° to -30° °C. This can be assisted with liquid nitrogen, tetrafluoroethylchloride, or methoxynonafluorobutane until the medium freezes (visually turns opaque), as seen in [Figure 29-12](#).

Figure 29-12. (A) Tissue is covered with an embedding compound, here OCT, which stands for “optimal cutting temperature.” Each case can be assigned a separate color of embedding medium. Yellow embedding medium is being used here. This is one way to maintain patient identification from two different sites or from two different patients. (B) The slide is submerged in the bath with a pair of tongs. The bath maintains temperature of approximately -30°C .

3. Place a small amount of embedding medium on the cryostat chuck (Fig. 29-13).

Figure 29-13. The chuck is prepared on the freeze bar with embedding medium, here optimal cutting temperature medium (OCT).

4. Invert the specimen (which is still on the glass slide) onto the chuck to create a final block. Additional embedding media can be added to the slide ([Fig. 29-14](#)). This allows the specimen to freeze to the chuck within the cryostat. A copper fitting or heat sink can be applied onto the slide. After a few minutes, the slide is removed. This reveals a smooth, level block face that should permit the deep margin and epidermal edge to be exposed in a single plane for cutting with the cryostat.

Figure 29-14. (A) Additional embedding medium is added to the tissue. (B) The specimen is placed upside down on the chuck with more embedding medium. It is allowed to cool further. (C) A heat sink or extractor is used to speed up the freeze process. After a few minutes, one can pop the slide off the tissue for embedding, leaving the surgical margin of the tissue exposed, all in one plane. If the slide resists popping off the embedding medium and tissue, a warm thumb can be used to warm the glass slide to separate it from the frozen block. A film of embedding medium can be applied to fill any open gaps in the block face for smoother sectioning and to prevent tissue from chunking out.

5. Place the specimen block in the cryostat to begin cutting the tissue (Fig. 29-15).

Figure 29-15. Once the slide is off, the chuck is ready to be placed in the object holder of the microtome. It is screwed down by the arm with the black/silver knob and then the angle of the tissue to the blade is adjusted with the red handle to the direct right of the tissue.

If the tissue is frozen too slowly, ice crystals can leave holes in the tissue. Condensate that accumulates in humid conditions can also result in ice crystal formation that causes cracks and holes in the specimen. Curling of the specimen may occur if the cutting blade in the cryostat is not cold enough, or if there is high humidity in the room.

Fatty tissue may require intense freezing, which can lead to an increase in epidermal freeze artifact, tissue fractures, and specimen chipping.

Cutting and slide fixation

Once the specimen is embedded and frozen in the medium and mounted on the stage, it is sectioned in the microtome and placed on the slide (Fig. 29-16). The clamp usually has a ball-and-socket joint that allows for minor adjustments in specimen alignment with respect to the blade, and one must ensure proper angle of blade prior to trimming into the block. When first beginning to rotate the microtome blade, the outer layers of OCT must be cut away until reaching the actual specimen; this procedure is often termed *facing the block*. Upon reaching the specimen, it may require realignment to create uniform slides. If the undersurface of the specimen on the chuck is not parallel to the blade early in the cutting, incomplete sections and consequent deeper sectioning requirements may result. Once the embedding medium has been adequately trimmed, horizontal 5- to 10-micron sections (section depth varies with personal preference) are affixed to the slides. Thick sections are difficult to read as cellular detail may be obscured, although fatty tissue may call for thicker sections, while thin sections may introduce holes or tears that are visible. The first slide is of utmost importance as it represents the true margin, since the tissue is cut from the deep margin upwards toward the surface of the skin with each turn of the blade. Ensure that the technician counts the number of turns of the wheel and knows the number of microns per turn in order to properly calculate the depth of the tissue. On average, two slides are made with two to three sections per slide. Most surgeons like to see three to six sections total.³²

A

B

Figure 29-16. (A) Sections are taken on the roller plate by turning the cryostat wheel. (B) The brush is sitting on the roller plate. Horizontal sections are taken in a bottom-up approach so that the first few sections are a representation of the true surgical margin comprising both skin edge and deeper tissue. (C) The tissue is then transferred to a glass slide.

Of note, fat does not become solid enough to cut well at temperatures that are best for cutting most other tissues. The technician may, therefore, spray the embedded fat-containing specimen with a cryogen to lower its temperature before cutting, rather than resetting the cryostat temperature.

Nearly all problems with wrinkling and folding arise when the specimen is advanced across the blade and when picking up the wafer for placement onto the slide; therefore, the technician must ensure that the cut wafer is properly retrieved. There is a tendency for frozen tissue to curl before it is placed on a glass slide. The curling can be mitigated by the use of antiroll bars (which prevent specimens from curling out of the plane of section) or plates, and/or camel hair brushes, which are kept in the cryochamber on the brush shelf.

Dull blades can cause tearing or curling of the tissue, or even lead to chatter lines in the tissue as they cut. A microscopic nick in the edge of the blade can create a large tear in tissue. Therefore, it is important to check the blade for nicks, and to sharpen the permanent blades and move disposable blades along the blade holder throughout the day.

If the blade is not clean, floaters may be introduced by the blade. These floaters may be present on multiple slides and can therefore be difficult to recognize as floaters.

When sliding sections from the blade onto the slide, additional errors may occur. After placing each section on the slide, extra embedding medium should be wiped off the glass slide before placing the subsequent section. If the next section is placed over the embedding medium of the previous section, it may not adhere properly during fixation and can be washed off during staining. If the next section overlays embedding medium over the

previous section, it may interfere with proper staining. To prevent this, when applying more than one section to a slide, it is common to begin in the upper corner and place sections diagonally across the slide.

Excessive facing of block produces false-negative and false-positive reads. If the specimen is not properly flattened, and a high area of tissue is cut away, then the true margin is forever lost. If the true margin contained tumor, a false negative may result. If the true margin was free of tumor, a false positive may result. Always use high-quality glass slides, as if glass slides are flawed tissue may not adhere properly. Charged slides (so-called *plus slides*) may be used to improve tissue adherence.

Staining

Slides must be stained so that the otherwise colorless cellular material can be visualized through a light microscope. Mohs slides are generally stained with hematoxylin and eosin (H&E), toluidine blue, or occasionally with special immunohistochemical stains for routine histologic analysis. H&E is the most commonly used tissue stain in MMS. This involves placing the tissue in a series of solutions: alcohol, water, xylene, hematoxylin, and eosin. In high-volume laboratories using H&E, they are placed in an automatic slide stainer to decrease the processing time (Fig. 29-17). Toluidine blue highlights islands of BCC by metachromatically staining its surrounding mucopolysaccharides a vibrant pink.³³ After the slides have been stained, they are cover-slipped. A glue-like medium is applied, followed by a thin glass cover slip that protects the tissue from being accidentally scratched off and preserves the slide for years.

Figure 29-17. Automated hematoxylin and eosin staining device with three slides being actively stained. Once the tissue section is picked up off the roller plate by pressing one of the relabeled slides to it, the slide is stained. The stain sequence is shown above. The slide transitions from fixatives, to hematoxylin, to bluing agent, to eosin, to alcohols, to xylene. Finally, the slides are coverslipped, matched with the requisition, and presented to the Mohs surgeon for interpretation.

If slides are moved too quickly from the fixative (usually alcohol), they will not dehydrate appropriately, resulting in suboptimal staining.

Immunohistochemistry is also used by some surgeons for treating more challenging tumors. These include cytokeratins for SCC and Paget's disease and CD34 for dermatofibroma sarcoma protuberans.^{34,35} For melanoma, frozen section interpretation can be facilitated by HMB-45,³⁶ MART-1, and S-100 for desmoplastic subtypes,³⁵ MITF for its superior nuclear staining,³⁷ and mel 5.³⁷ Overall, MART-1 is the most useful stain for melanoma.³⁸ The cost of reagents, unavailability of automated staining equipment, additional processing time, and additional technician skill and time, have slowed the widespread adaptation of immunostains by Mohs surgeons.³⁹ Regardless of whether immunostains are used during Mohs surgery, permanent sections may be obtained for additional confirmation of clear margins in more challenging

cases. A full discussion of immunohistochemical stains for MMS may be found in [Chapter 30](#).

During staining, a floater can be introduced from contamination of the staining solution. This floater will randomly appear (not necessarily contiguous with the specimen). Changing the staining solution regularly minimizes the introduction of floaters.

Mapping the tumor and interpreting the slides

The names and accession numbers on the slides should be checked to be sure that they correspond to the names and accession numbers of the Mohs maps on which the interpretation of these slides is to be entered. Only after ensuring the correct slides are being read may the Mohs surgeon begin to interpret the slides.

Interpretation of Mohs slides is the most critical step in MMS; a technically superior section is demonstrated in [Figure 29-18](#). Scanning of Mohs slides should evaluate all tissue sections on the slide in a systematic way by examining all the peripheral and deep margins. Verify that a complete epithelial edge and deep margin are present. Mohs surgeons should be facile in identifying different cutaneous structures and in detecting various skin neoplasms, skills that are teachable, and consistently improve with training and experience.⁴⁰

Figure 29-18. Hematoxylin and eosin stain of a frozen section depicting the excised surgical margin. The inks used are clearly visible, and the epidermis, dermis, and subcutaneous fat are all seen and evaluated in the section. In this case, no tumor is seen.

Errors may occur by misinterpreting floaters as positive margins (Fig. 29-19); misinterpreting benign structures such as hair follicles, parotid gland, lymph nodes, and other adnexal neoplasms as BCC (Fig. 29-20); misreading actinic keratosis or scar as SCC; mistaking granulation tissue or fibrosis for a spindle cell neoplasm; and reading benign structures such as seborrheic keratoses and warts as SCC (Fig. 29-21). Certain anatomic areas, such as the eyelid, have unique histology, particularly when read in horizontal sections, that can be misinterpreted as tumor (Fig. 29-22).

Figure 29-19. Floaters may be introduced during curettage, nicking, cutting tissue, and staining tissue. (A) 10× and (B) 20× views.

Figure 29-20. The dark blue cells of the parotid gland can be mistaken for tumor. (A) 4× and (B) 10× images of parotid tissue reveal glandular elements not seen in BCC. Note lack of palisading and retraction artifact. (C) View of a Mohs section showing a follicular basaloid proliferation with irregular

strands of basaloid cells emanating from a hair follicle. It has a characteristic pin wheel appearance. There is also lack of cleaving adjacent to the cells, apoptosis or mitotic figures as well as the presence of a fibrous sheath.

Figure 29-21. (A) Squamous cell carcinoma, which can be confused with (B) a seborrheic keratosis. (C) A focus of dense inflammation around a hair follicle can also be misread as a positive margin. Additional cuts usually reveal a benign structure.

Figure 29-22. (A) Conjunctiva with meibomian glands and ducts 4×. (B) 20× mucus-producing goblet cells of the conjunctiva may be misinterpreted as melanocytes, Paget's disease, or Bowen's disease. (C) Apocrine gland of Moll 40×. (D) Pyknotic muscle fibers may simulate SCC, especially when viewed singly. Note the preserved lobular architecture.

The success of MMS is contingent upon the presence of high-quality frozen tissue sections, and artifacts may make reliable slide interpretation challenging (Fig. 29-23). Recognizing the artifact allows the Mohs surgeon to account for it and make the correct interpretation. Overlooking a section of tissue or evaluating a suboptimal slide with missing tissue or containing a substantial hole has been associated retrospectively with tumor recurrence.²⁵

Figure 29-23. Technical errors with slides. (A) Missing epidermis. (B) A large recurrent cancer with epithelium from the center of the specimen implanted into the deep margin of the Mohs section, mimicking a positive deep margin. (C) A chatter line from a defect in the blade.

If a positive margin is detected, the Mohs surgeon marks the positive areas on the two-dimensional map (Fig. 29-24). An additional layer of skin is excised in the area where tumor was identified. This is accomplished by noting the inked nicks and corresponding sites marked on the map. The process of excising, mapping, and sectioning additional layers of skin is repeated until no additional tumor is identified. Subsequent layers are taken only in the areas involved by tumor with an overlap width of 1 to 3 mm in order to maximally spare uninvolved tissue. Once negative margins are achieved, appropriate reconstruction can be contemplated.

Figure 29-24. (A) A focus of basal cell carcinoma is seen between the red and yellow nicks on stage 1. (B) This is indicated with red pencil on the map. A second layer is taken in the area with tumor and is indicated on a separate map to the right of stage 1. (C) The second stage is clear of tumor, so no red penciled areas are seen on the map for stage 2.

Inflammation may make minute cancer foci challenging to see. Requesting thinner slide sections may help, though with aggressive tumors, immunohistochemistry (either on permanent sections or on frozen Mohs sections) can be occasionally helpful. Patients with a history of chronic lymphocytic leukemia or solid organ transplant have a 36% and 13% incidence, respectively, of prominent inflammatory foci on Mohs sections compared with controls (1%), making slide interpretation more difficult.⁴¹

Some Mohs surgeons prefer to limit the use of electrocautery, as excessive cautery may lead to elongation of the nuclei and cytoplasm of epidermal cells and adnexa, as well as basement membrane retraction artifact, histologically mimicking BCC. Moreover, cautery induces local inflammation that may be challenging to distinguish from tumor-induced inflammatory reactions.

Additionally, if the tumor has excessive epidermis centrally (as can happen with recurrent tumors and/or partially treated tumors), these cells may be pushed up to the surface and be misinterpreted as residual tumor.

When approached with the difficulty of determining the distinction between basaloid follicles and tumor, serially sectioning of the tissue specimens allows one to further differentiate normal adnexal structures from tumor nests.

When taking an additional Mohs stage due to the presence of a positive margin on a previous stage, the surgeon should overlap the diagrammed extent of the positive margin to provide a margin of error. Keep in mind that frozen tissue section processing results in approximately 10% to 20% tissue shrinkage.

If perineural invasion is seen, the subsequent stage must include *both* peripheral and deep tissue, *and* the nerve must be visualized in the subsequent stage, before that margin can be called clear. This is because nerves can travel vertically or horizontally. Examples can be seen in [Figures 29-25](#) and [29-26](#).

Figure 29-25. Perineural involvement. Basal cell carcinoma with a halo of basal cells invading a cutaneous nerve. (A) 20× demonstrating BCC invading a nerve on frozen section. (B) S100 stain on permanent section highlighting the nerve stained brown with BCC within the nerve sheath. (C) 40× permanent section of the same nerve seen in A and B. (D) S100 stain demonstrating a large nerve invaded by BCC. (E) Permanent section of the same BCC invading the large nerve seen in D.

Figure 29-26. (A) SCC surrounding a nerve fiber on frozen section at 20×. (B) Immunohistochemistry demonstrates the nerve, stained brown with S100, is uninvolved with SCC, which is stained red with cytokeratin. This can be easily misinterpreted as perineural invasion of SCC on frozen section. IHC was necessary to make a diagnosis in this case. (C) A permanent section of the same field is provided for comparison.

ADVANTAGES OF MOHS SURGERY OVER EXCISION

Cancer surgery is predicated on the assumption that tumor growth is spherical, a theory that is not entirely accurate for many cutaneous tumors. This model does not account for embryonic fusion planes and other tissue planes that may present a temporary barrier to tumor spread. As a consequence of this, the growth and configuration of skin cancers are often asymmetrical and irregular. Such asymmetrical tumors are better removed with MMS with its attendant meticulous and precise tumor removal.

In conventional processing of excisions, histologic sections are generally obtained vertically using a bread-loafing technique. This involves *sampling* sections of skin, and is estimated to examine only 0.1% to 1% of the total

histologic margin, and can therefore result in false-negative results. This contrasts with the horizontal sectioning of Mohs surgery, which examines 100% of the margin. This approach, therefore, offers a clear advantage in lowering the chance of recurrence.

Furthermore, the mapping of 100% of the surgical margin allows the surgeon to precisely control all margins and adopt a tissue-sparing technique. By contrast, for BCCs less than 10 mm in diameter, conventional excision requires 4-mm margins to obtain a 95% cure rate and larger, sclerosing or recurrent BCCs required 13- to 15-mm margins to reach a 99% cure rate.⁴² These margins may unnecessarily involve anatomic structures, such as nerves, cartilage, tendons, and muscle. One study showed that the median area of the surgical defect produced during MMS for the treatment of nodular BCCs was significantly smaller than that of conventional surgical excision (116.6 mm² vs. 187.7 mm², $p < 0.001$),⁴³ facilitating a more straightforward repair of the defect. Using Mohs surgery to possibly conserve these structures enables the surgeon to conduct more sophisticated and perhaps more cosmetically elegant reconstructions immediately after resection.

COMPLICATIONS

Complications of Mohs surgery are rare, and are mostly related to post-Mohs reconstruction. These include some degree of bruising, swelling, scarring, dysesthesia, and postoperative discomfort. Rarely, edema and dysesthesia may be persistent, though this normally returns to baseline in a few to several months. All potential complications should be discussed with the patient prior to the initiation of surgery.

Bleeding

Bleeding is the most common post-Mohs surgery complication, and its risk is increased in patients taking anticoagulants. Still, there is no evidence that patients taking aspirin or warfarin for serious medical problems experience increased risks of *serious* hemorrhage or bleeding complications. Patients on thienopyridines such as clopidogrel or ticlopidine undergoing dermatologic surgery are, however, at increased risk of bleeding complications.^{44,45} These minor complications include partial necrosis in 1.7% of flap closures and

8.6% of graft closures (with no instances of complete necrosis or need for subsequent revision), and a 0.73% rate of dehiscence. Such complications are generally managed straightforwardly in the outpatient setting. Therefore, medically necessary anticoagulants are typically continued in the perioperative period in order to prevent thrombotic events.

Infection

If a Mohs wound is left open to heal by secondary intention, the rate of infection is very low. For example, Lawrence et al. allowed 67 relatively large wounds left open to heal by the second intention following skin cancer excision and observed infection in only two cases,⁴⁶ and Mohs surgeons are generally skilled at assessing whether a wound is appropriate for secondary intention closure.⁴⁷ Most studies examining infection rates, however, include both Mohs surgery and reconstruction. Wounds sutured closed create dead space and introduce foreign material into the wound, making them more likely to become infected. Despite this, infection occurs in only 1% to 2% of cases,^{48,49} with higher rates seen in patients with excessive bleeding or hematoma formation. Some studies have suggested that intra-incisional injection of nafcillin or clindamycin after Mohs surgery and prior to surgical reconstruction may reduce the risk of postoperative infection.^{50,51} Prophylactic antibiotics are not routinely recommended unless there is high risk of infective endocarditis, hematogenous joint infection, or surgical site infection.¹⁹

Scarring

Scarring from MMS is often seen as the most significant sequela of the procedure from the patient's perspective, and is dependent on both the extent of tumor-induced tissue destruction and closure technique. Hypertrophic scarring, keloids, widened scars, and scars demonstrating pigmentary changes are all possible, and counseling the patient prior to surgery is imperative in setting appropriate patient expectations.

Nerve damage

Sensory nerve loss often occurs during Mohs surgery, because small sensory fibers are severed during tumor excision. Such deficits are usually short term owing to regeneration of the nerve fibers. Motor nerve damage may occur when tumors invade or surround the nerve and must be sacrificed. Regardless, a detailed knowledge of anatomy is important to avoid these structures when possible and to warn patients when nerve compromise may be imminent.

Lidocaine toxicity

Lidocaine toxicity must be avoided during MMS. Careful record keeping is critical, especially in large tumors that require several stages to clear. Clinical signs of lidocaine toxicity include talkativeness, perioral paresthesias, tinnitus, vomiting, tremors, seizures, and ultimately cardiopulmonary arrest. To prevent this complication, the maximum lidocaine dose in adults of 5 mg/kg for plain lidocaine and 7 mg/kg for lidocaine with epinephrine should be observed.

Cerebral emboli

Lethal complications of Mohs surgery are rare, but two cases of cerebral emboli have been described following MMS for scalp tumors.⁵² To prevent this complication, patients with exposed calvarium (stripped periosteum) require careful patient positioning in the supine or prone position to limit negative pressure gradients that may occur via the noncollapsing veins of the head and neck such as the epiploic veins and the emissary veins that drain to the dural venous sinuses. The majority of neck and scalp incidences of air embolism occur via the posterior venous complexes; therefore, caution should be taken with Mohs defects with stripped periosteum on the posterior scalp to keep these patients flat during surgery and while waiting in between stages.⁵³

NEW DIRECTIONS

Evidence supports the use of MMS for the treatment of melanoma and rarer cutaneous malignancies, such as dermatofibrosarcoma protuberans, atypical

fibroxanthoma, microcytic adnexal carcinoma, malignant fibrous histiocytoma, adenocystic carcinoma, apocrine/eccrine carcinoma, mucinous carcinoma, leiomyosarcoma, and sebaceous carcinoma.⁶ Among these tumors, MMS is being increasingly used as an alternative to standard excision for certain melanomas. Melanocytes are difficult to assess on routine frozen section,³⁸ but with advances in immunohistochemistry, Mohs surgeons overcome this challenge by using special stains that better highlight these cells. Kelley et al. reported 100% correlation between paraffin-embedded permanent sections and frozen sections stained with MART-1.⁵⁴ As laboratory-staining techniques improve, Mohs surgery may play an increasing role in the treatment of melanoma. For a full discussion of Mohs approaches to melanocytic lesions, see [Chapter 31](#).

CONCLUSIONS

Understanding the fundamental techniques of MMS permits the physician to appreciate the specific instances when patients will best benefit from this procedure. The techniques of MMS have continued to evolve since its introduction by Dr. Frederic Mohs, and some variation persists between Mohs surgeons. A significant benefit of this approach is that the Mohs surgeon serves as the pathologist, lowering the potential for human error in a situation where tissue orientation is of critical importance. The accuracy and skill applied at each step of the procedure lead to the consistently high cure rates balanced by maximal tissue conservation. Newer directions, particularly the use of immunohistochemical stains to permit effective treatment of melanoma, continue to permit this technique to remain at the cutting edge of dermatologic surgery and surgical oncology.

Acknowledgments

I would like to thank the histotechnicians at Saint Louis University, particularly Tom Scagliarini and Julie Schuette, for assisting with photographs and videos of their work. I would also like to thank Dr. Russell Tipton from the Saint Louis University Department of Dermatology and Dermatopathology and Dr. Daniela Hermelin from the Saint Louis University

Department of Pathology for help taking photographs of slides used in this chapter.

CHAPTER 30 Advanced Techniques and Special Stains in Mohs Micrographic Surgery

**Jessica M. Donigan
Benjamin Jones
Alice Frigerio
Keith L. Duffy**

SUMMARY

- Micrographic surgeons must have a working knowledge of pathology techniques including immunohistochemical stains and newly developed and developing molecular diagnostics.
- From a practical standpoint, with the exception of lentigo maligna (and potentially superficially invasive melanomas), there are few tumors that benefit from the addition of frozen section immunohistochemistry at the time of micrographic surgery.

Beginner Tips

- Maintain regular contact with colleagues in dermatopathology. The perspective of the pathologist and surgeon must be mutually understood.
- Personal visits are better than phone calls which are better than e-mails which are better than text messages.

Expert Tips

- Poorly differentiated tumor cells, dense inflammation, perineural invasion, and fibrosis are all situations in which immunohistochemical stains may be useful. The most widely used is AE1/AE3, a pan-keratin marker, which will label most carcinomas.
- If there is specific concern for BCC, a Ber-EP4 stain can be performed.
- CK7 for EMPD may be helpful in Mohs frozen sections. The main caveat to using this stain is the usually large sizes of the pieces of tissue to be examined in EMPD.

Don't Forget!

- New terms are introduced into the literature by both clinicians and pathologists in an attempt to better define pathological entities and stratify risk. In recent years, the terms atypical intradermal smooth muscle neoplasm (instead of cutaneous leiomyosarcoma) and pleomorphic dermal sarcoma/undifferentiated pleomorphic sarcoma have been introduced. Pleomorphic dermal sarcoma/undifferentiated pleomorphic sarcoma is a distinct entity from AFX and has a worse prognosis.

Pitfalls and Cautions

- CD34 as a frozen section immunohistochemical stain for DFSP treated by MMS is discouraged. The nonspecific background staining, as well as the labeling of endothelial cells, makes this extremely difficult to interpret on frozen section pathology.
- Some tumors may also benefit from adjuvant therapy, such as postoperative radiation.

Patient Education Points

- Patients should be explained that many rarer or more aggressive tumors have a high defect to lesion ratio, so an ostensibly small tumor may end up leading to a very large defect.
- The high cure rates cited for Mohs surgery are generally applicable to primary low-risk tumors; tumors with negative prognostic factors (infiltrative or perineural patterns) or unusual tumor types (Merkel cell carcinoma, DFSP) may be associated with significantly higher recurrence rates.

Billing Pearls

- Billing for immunohistochemical stains is in addition to standard Mohs layer billing, and is generally billed on a per-specimen basis with code 88342 for the first antibody followed by 88341 for each additional antibody. If multiple separately identifiable antibodies are applied to the slide, use one unit of 88344.

CHAPTER 30 Advanced Techniques and Special Stains in Mohs Micrographic Surgery

INTRODUCTION

Even in the busiest Mohs micrographic surgery (MMS) practice or at a tertiary/quaternary referral center, special stains are not used on a frequent basis. Treating these cases not only requires a technically proficient micrographic surgeon and laboratory, but also the knowledge of the latest pathology techniques and available immunohistochemistry stains for both permanent and frozen section pathology. While the ability to see 100% of the surgical margin using the MMS technique is certainly an advantage, there are limitations to both this technique and the use of frozen section pathology in certain circumstances. For the specialized tumors discussed in this chapter, both good judgment and an excellent working relationship with a colleague in dermatopathology are a necessity.

ROUTINE STAINS

Hematoxylin and eosin (H&E) is the mainstay of MMS staining, and toluidine blue is widely used in certain corners of the MMS community. It is likely that familiarity with the stain leads to high confidence in tumor detection and cure rates with either stain.

Both toluidine blue and H&E have been used from the 1800s and have remained popular in both permanent section pathology and frozen section pathology to the present day. Hematoxylin is derived from the logwood tree (*Haematoxylum campechianum*), native to Central America and the West Indies. It was initially used as a dye and first reported in tissue staining in 1865.¹ Toluidine blue (also known as tolonium chloride) was discovered in 1856 and also used as a dye.² Eosin, the potassium salt of tetrabromofluorescein, was synthesized in 1871,³ and dual staining with H&E was first reported in 1876.⁴

A survey study reported that 17% of Mohs surgeons use toluidine blue for detection of basal cell carcinoma (BCC) in MMS.⁵ Toluidine blue produces characteristic metachromatic staining of the mucopolysaccharides in the stroma of BCC, producing a magenta color (Fig. 30-1). This highlighting of the stroma and BCC draws the eye of the Mohs surgeon. The metachromatic staining in the stroma of BCC allows easy differentiation of basaloid follicular epithelium from BCC. The other advantage of using toluidine blue is a more rapid staining than H&E. A variety of rapid protocols have been published in the literature.^{5,6}

A

B

Figure 30-1. Infiltrative basal cell carcinoma. (A) Staining with hematoxylin and eosin (40×). (B) Staining with toluidine blue of the same tumor; notice, the metachromatic (**magenta**) staining of the associated stroma (40×). (Used with permission from David Zloty, MD).

Some have also argued that toluidine blue is not inferior to H&E staining for the detection of squamous cell carcinoma (SCC),⁷ and the concurrent use of both toluidine blue and H&E may improve diagnostic accuracy in MMS.⁸ Ultimately, familiarity with the stain appears to be the most important driver of tumor detection.

IMMUNOHISTOCHEMICAL STAINS

While recognizing SCC and BCC on frozen sections stained with H&E or toluidine blue is usually straightforward, there are certain situations when it may be difficult to clearly distinguish residual tumor cells, potentially resulting in unnecessary additional layers, or tumor recurrence. Such situations include poorly differentiated tumor cells, dense inflammation, perineural invasion, and fibrosis.^{9,10} These situations are also encountered during the treatment of rarer tumors such as dermatofibrosarcoma protuberans (DFSP) and extramammary Paget's disease (EMPD). It is in these cases of high-risk or difficult tumors that immunostains can be used in addition to routine staining to aid the surgeon in identifying residual tumor.

Immunostaining in MMS was first reported in 1984¹¹ and has since become more reliable, cost effective, and efficient, contributing to its usage nearly doubling in the last 12 years.¹² Immunohistochemistry allows the visualization of specific antigen(s) in tissue using light microscopy. This can be performed using a one-step direct method, or a two-step indirect method. In both the direct and indirect methods, an enzyme conjugated to the primary or secondary antibody, respectively, catalyzes a chromogen, which in turn acts as a stain that can be visualized.¹³ Immunostaining requires a skilled histotechnician, as sections should be 4 µm in thickness or less, due to the potential for thicker sections to hold the stain, increasing nonspecific staining.¹⁰ More rapid immunostaining techniques may also increase background and nonspecific staining, making the use of negative controls necessary.⁹ While multiple antigens may be positive in cutaneous tumors

(Table 30-1), certain immunostains are more useful than others in identifying specific tumor cells.

Table 30-1. Immunostains for Tumors Treated with Mohs Micrographic Surgery^{10,14–17}

Neoplasm	Immunostain	
	Positive	Negative
Squamous cell carcinoma	Cytokeratins (AE1/AE3, MNF116, CK5/6), p63	S100, HMB-45, Melan-A, SMA, desmin, CD10, CD31, CD34
Basal cell carcinoma	Cytokeratins, Ber-EP4	EMA
Dermatofibrosarcoma protuberans	CD34	Cytokeratins, factor XIIIa, S100, desmin, SMA
Extramammary Paget's disease	CK7, CEA, EMA, GCDFP	S-100, Melan-A
Microcystic adnexal carcinoma	AE1/AE3, EMA, CEA	CK20, Ber-Ep4
Sebaceous carcinoma	AE1/AE3, CK7, Cam 5.2, EMA, BER-EP4, adipophilin, androgen receptor	CEA
Atypical fibroxanthoma	CD10, CD68, procollagen-1, alpha-1-antitrypsin	Cytokeratins, p63, CD34, S100, HMB-45, Melan-A, desmin
Merkel cell carcinoma	CK20, MNF116, synaptophysin	TTF-1
Atypical intradermal smooth muscle neoplasms (cutaneous leiomyosarcoma)	SMA, desmin	Cytokeratins, CD34, S100, HMB-45, Melan-A
Porocarcinoma	CEA, EMA, adipophilin, CD117	S-100

SMA, smooth muscle actin; CEA, carcinoembryonic antigen; EMA, epithelial membrane antigen; GCDFP, gross cystic disease fluid protein.

Cytokeratins

Cytokeratins, or simply keratins, are intermediate filaments that play a role in the structural integrity and resilience of the epidermis. They are found in nearly all epithelial cells, but not in nonepithelial cells such as fibroblasts, muscle cells, or neurons,¹⁸ and are therefore useful in identifying tumor cells derived from the epidermis.¹⁰ Cytokeratins are classified by their molecular weight or pH. Low-molecular-weight cytokeratins include CK7, 8, 18, 19, and 20, while CK1, 2, 5, 9, 10, and 14–17 are high-molecular-weight cytokeratins. Type I (acidic) cytokeratins include CK9–19 and type II (basic) group is composed of CK1–8. Glandular epithelium is composed of low-to intermediate-molecular-weight keratins, and squamous epithelium of primarily high-molecular-weight keratins.¹³

AE1/AE3 is a pankeratin stain that recognizes cytokeratins between 40 and 67kDa in molecular weight. The AE1 antibody binds to CK10, 14–16, and 19, while AE3 binds to CK1–8.¹⁸ SCC expresses CK5, 6, 8, 14, 17, and 18, while BCC expresses CK5, 14, 15, and 17.¹³ The AE1/AE3 cocktail will thus stain most SCCs and BCCs and can be useful in cases where there is residual tumor in areas of heavy inflammation (Fig. 30-2), perineural spread

(Fig. 30-3), or extension into fascia.^{19,20} AE1/AE3 is also an effective choice for staining microcytic adnexal carcinoma (MAC) and sebaceous carcinoma.¹⁴

Figure 30-2. Squamous cell carcinoma with dense inflammation (400×). (A) Hematoxylin and eosin. (B) AE1/AE3 stain demonstrates carcinoma cells within inflammation. (Used with permission from Thuzar M. Shin, MD, PhD).

Figure 30-3. Squamous cell carcinoma with perineural invasion (100×). (A) Hematoxylin and eosin. (B) AE1/AE3 stain makes perineural tumor cells much more easily identifiable. (Used with permission from Thuzar M. Shin, MD, PhD).

MNF116 is a monoclonal antibody that detects both low- and high-molecular-weight cytokeratins (CK5, 6, 8, 17, and 19). It shows cytoplasmic staining and is positive in all cutaneous lesions with epithelial differentiation including SCC, BCC, adnexal tumors, and Merkel cell carcinoma (MCC).²¹ MNF116, particularly in combination with p63, may be a sensitive stain for poorly differentiated SCC.²²

CK7 is a low-molecular-weight cytokeratin and is a specific, intense stain for Paget cells as well as the immunostain of choice for EMPD.²³ Sebaceous carcinoma may also express CK7.²⁴

Cam 5.2 stains for the low-molecular-weight cytokeratin CK8, and to a lesser extent, CK7.²⁵ It can be very useful in identifying sebaceous carcinoma and distinguishing it from benign sebaceous neoplasms, SCC, and BCC.²⁶ Cam 5.2 staining is also positive in primary cutaneous mucinous carcinomas.¹⁴

CK20 is a low-molecular-weight cytokeratin and is frequently used in the diagnosis of MCC.

Ber-EP4

Ber-EP4 is a monoclonal antibody against human epithelial antigen and binds a glycopolypeptide on the surface and within the cytoplasm of epithelial cells.¹⁴ Ber-EP4 is useful in differentiating BCC from SCC, and although the antigen is found in adnexal structures such as apocrine and eccrine glands, aside from the base of the hair bulb, Ber-EP4 is generally absent in hair follicles, making it useful in differentiating BCC from hair follicles.²⁷ Ber-EP4 can be helpful in identifying BCC tumor cells in difficult cases where there is dense inflammation, perineural disease, or an infiltrative component.²⁸

CD10

CD10, also known as the common acute lymphoblastic leukemia antigen (CALLA), is a cell-surface glycoprotein found on hematopoietic progenitor cells and nonhematopoietic cells.¹⁶ Strong and diffuse staining of atypical fibroxanthoma (AFX), including perifollicular extension, has been demonstrated with CD10.^{16,29} However, spindle-cell SCCs can also stain strongly for CD10. These tumors can be differentiated with additional immunostains, as SCC should be positive for cytokeratins and p63.¹⁶

CD34

CD34 is a transmembrane glycoprotein found on dermal dendritic cells, as well as endothelial and hematopoietic progenitor cells.^{30,31} It is commonly used to differentiate DFSP from other fibrous tumors, particularly dermatofibroma, but also AFX, fibrosarcoma, and nodular fasciitis.³² It has been useful in the treatment of DFSP with MMS, as tumoral spindle cells can be difficult to distinguish from normal fibroblasts.³¹

Carcinoembryonic antigen

Carcinoembryonic antigen (CEA) encompasses a set of glycoproteins involved in cell adhesion. CEA levels are elevated in various malignancies, making it useful as a tumor marker for select cutaneous malignancies. CEA has been shown to identify ductal structures in MAC.³³ Paget cells can have variable staining with CEA, but it can be useful in distinguishing EMPD from adjacent intraepidermal dysplasia.³⁴ CEA also labels eccrine and apocrine cells which can be used as an internal control.¹³

Epithelial membrane antigen

Epithelial membrane antigen (EMA) is a glycoprotein expressed on secretory epithelia. EMA can highlight epithelial cells and ductal structures in MAC.³³ EMA is positive in sebaceous carcinoma, but can also be positive in SCC, and is therefore not as useful a stain as Cam 5.2 for sebaceous carcinoma.²⁶ EMA may also stain Paget cells.¹⁵

Adipophilin

Adipophilin, also known as adipose differentiation-related protein or perilipin 2, is a protein required for the formation and maintenance of lipid droplets. Although its expression is nearly ubiquitous, it has been reported to be a sensitive marker for sebaceous carcinoma.^{24,35} Adipophilin expression is also seen in a variety of other tumors including SCC with clear cell change, eccrine–apocrine carcinomas,³⁵ and malignant melanoma,³⁶ indicating that lipids are necessary for cellular proliferation with a possible correlation between the expression of adipophilin and the proliferative

potential of cancer cells.³⁶ Although other cutaneous malignancies may express adipophilin, a globular staining pattern, as typically expressed in cells with sebaceous differentiation, may be more specific for sebaceous carcinoma. SCC, sweat gland (eccrine and apocrine) carcinomas, and malignant melanoma tend to have more granular staining.^{35,36}

p63

p63 is a member of the *p53* gene family and may play an essential role in regulating the development and differentiation of the epidermis. It is a nuclear marker expressed in the epidermis, eccrine ducts, sebaceous glands, and myoepithelial cells of the eccrine and apocrine glands.³⁷ p63 is overexpressed in SCC and is therefore thought to act as an oncogene.³⁷ p63 staining can be useful in differentiating spindle-cell SCC from other spindle-cell neoplasms such as AFX and melanoma.^{16,22,37}

RARE TUMORS TREATED WITH MOHS MICROGRAPHIC SURGERY

MMS is most frequently utilized in the treatment of SCC and BCC, as these are the most common cutaneous malignancies. However, there are other tumors for which MMS is an appropriate therapy. A multidisciplinary approach to rare cutaneous tumors may result in the best outcomes for patients.

Dermatofibrosarcoma protuberans

DFSP is a slow-growing, locally aggressive soft tissue tumor with an incidence of 4.2 per million (0.1% of all cancers).³⁸ There is a higher incidence in African Americans.³² DFSP occurs most frequently on the trunk, followed by the proximal extremities, and then the head and neck.³² Histopathologically, DFSP appears as a proliferation of spindle cells in the dermis with projections that can extend into neighboring collagen bundles and underlying fat, as well as muscle and fascia (Fig. 30-4). These

extensions can make complete removal difficult, with recurrence rates as high as 60% reported after wide local excision (WLE).³² While the overall recurrence rate after WLE may be closer to 7.3%, there is currently no consensus regarding the most appropriate surgical margin,³² with 5-cm margins potentially leaving residual tumor in 5.2% of cases.³⁹ Uncertainty regarding adequate margins and high recurrence rates, particularly of tumors located on the head and neck, led to the utilization of MMS in the treatment of DFSP, where recurrence rates ranging from 0% to 6.6% have been reported.⁴⁰ In a recent study, DFSP treated with MMS was nine times less likely to have recurrence compared with those treated with WLE.⁴¹ Surgeons and patients should be aware that the defect size is often much larger than the original lesion, with a defect to lesion size ratio of 7.7 reported in one report (Fig. 30-5).⁴⁰

Figure 30-4. Dermatofibrosarcoma protuberans. Hematoxylin and eosin. (A) Spindle cells in the dermis (200×). (B) Projections into underlying fat leading to honeycombing (100×).

Figure 30-5. Dermatofibrosarcoma protuberans. (A) DFSP on the cheek prior to undergoing Mohs micrographic surgery. (B) Mohs defect; note the increase in size compared to the clinical lesion.

CD34 immunostaining can be used to differentiate DFSP from other fibrous tumors (Fig. 30-6). It may also be useful in determining clear margins during the treatment of DFSP with MMS, particularly in cases where there are areas of scarring.³¹ While CD34 is a valuable stain in DFSP, there can be variable staining in these tumors,³⁰ with negative staining sometimes seen in the nodular portions of DFSP.¹⁴ Nonetheless, CD34 remains the most practical immunostain to be used in MMS for DFSP.¹⁴

Figure 30-6. Dermatofibrosarcoma protuberans (200×). (A) Positive CD34 staining can help differentiate these tumors from other spindle-cell neoplasms. (B) Negative factor XIIIa staining helps to

differentiate DFSP from dermatofibroma.

Extramammary Paget's disease

EMPD is a rare, slow-growing cutaneous adenocarcinoma that most commonly involves the female genitalia, particularly the vulva. In males, EMPD tends to involve the scrotum, with the penis and pubis involved less frequently.⁴⁰ Other areas of involvement include the perineum, axilla, and umbilicus.¹⁵ Clinically, EMPD presents as an ill-defined erythematous plaque (Fig. 30-7). Histopathologically, EMPD is characterized by large cells with abundant pale-staining cytoplasm (Paget cells) that may be found in clusters abutting the basal layer, as well as scattered upwards throughout the epidermis (pagetoid spread) (Fig. 30-8). The ill-defined clinical margins, along with microscopic extensions of tumor cells, can make complete excision of EMPD difficult, with no consensus on the most appropriate surgical margin. Recurrence rates of 20% to 60% have been reported following WLE.⁴² The utilization of MMS for EMPD has resulted in lower rates of recurrence, with reports ranging from 0% to 27%.⁴⁰ A systematic review and meta-analysis showed an overall EMPD recurrence rate of 12.2% following MMS.⁴² A defect to lesion size ratio of 3.2 has been reported.⁴⁰

Figure 30-7. Extramammary Paget disease presents as an ill-defined erythematous plaque. (Used with permission from Ali Hendi, MD).

Figure 30-8. Extramammary Paget's disease. (A) Hematoxylin and eosin stain demonstrates malignant Paget cells (200×). (B) Hematoxylin and eosin (100×). (C) Immunohistochemical stain for CK7. (B,C used with permission from Ali Hendi, MD).

Immunostains are important in the diagnosis of EMPD on permanent sections and can also be used on frozen sections during MMS. Paget's cells may stain with CK7, CEA, EMA, and gross cystic disease fluid protein (GCDFP). Of these stains, CK7 is the most sensitive and intense, and is therefore the immunostain of choice in the diagnosis of EMPD (Fig. 30-8).²³ CK7 has been used in the treatment of EMPD with MMS, but its effect on recurrence rate has not yet been published.¹⁵

Microcystic adnexal carcinoma

Microcystic adnexal carcinoma (MAC), also known as malignant syringoma or syringoid carcinoma, is another rare cutaneous tumor. MAC tends to occur on the central face of Caucasian individuals in the fourth to sixth decades.

Although asymptomatic with indolent growth, rare metastasis, and high survival rates, MAC can be locally aggressive and cause significant morbidity.⁴³ Histopathologically, MAC appears as multiple groups of basaloid epithelial cells, ductal structures, and keratinizing cysts, often infiltrating the superficial and deep dermis as strands of tumor woven through collagen bundles (Fig. 30-9).⁴⁴ Mitoses and cytologic atypia are not a predominant feature.⁴⁵ MMS has proven superior to WLE in treating MAC. Recurrence rates following WLE can range from 17% to 60%, while those after MMS range from 0% to 12%.⁴⁶ As with DFSP, the defect size is often much larger than what is clinically apparent, with a defect to lesion size ratio of 6.2 reported.⁴⁰

Figure 30-9. Microcystic adnexal carcinoma. (A) Low power demonstrating infiltrative nature of the tumor with syringoma-like structures and keratinaceous microcysts (H&E, 40×). (B) Small infiltrative strands of epithelial structures in the deeper portion of the tumor (H&E, 100×).

Immunohistochemistry can be vital in differentiating MAC from other neoplasms. CEA, EMA, and AE1/AE3 are most helpful in differentiating eccrine and pilar derivatives of MAC.^{14,33}

Sebaceous carcinoma

Sebaceous carcinoma is a rare, and sometimes, aggressive cutaneous tumor found most commonly in the periocular region (Fig. 30-10), representing 1% to 6.4% of all eyelid malignancies.⁴⁷ There is a higher frequency of sebaceous carcinoma in patients with Muir–Torre syndrome (MTS), a rare, autosomal dominant genodermatosis.⁴⁸ Histopathologically, sebaceous carcinomas appear as foamy cells with sebaceous differentiation (Fig. 30-11). Cellular atypia and mitotic figures are common, and pagetoid spread

may be seen. These tumors most commonly grow by direct extension and tissue invasion, but there may be multifocal growth with skip areas leading to margin involvement, and local recurrence rates of up to 36% following WLE with 5- to 6-mm margins have been reported.¹⁴ Treatment of sebaceous carcinoma with MMS can have better outcomes, with recurrence rates of 12% or less.⁴⁷ A defect to lesion size ratio of 4.7 has been reported following MMS.⁴⁰

Figure 30-10. Sebaceous carcinoma presenting as a yellowish erythematous papule on the upper eyelid. (Used with permission from Eva Hurst, MD).

Figure 30-11. Sebaceous carcinoma is characterized by foamy cells with sebaceous differentiation (H&E, 200×). (Used with permission from Eva Hurst, MD).

Immunohistochemistry can play a variety of roles in sebaceous carcinomas. Due to the association with MTS, immunostains for germline mutations in MLH1 (Fig. 30-12), MSH2, MSH6, and PMS2 (Fig. 30-12) may prove useful in some, as the loss of staining of these mismatch repair genes has a high positive predictive value for MTS.⁴⁸ AE1/AE3, EMA, CK7, cam 5.2, and adipophilin are positive in sebaceous carcinomas and can be useful in detecting intraepithelial spread, including nests and single-cell spread. Of these stains, cam 5.2 has the highest specificity for sebaceous carcinomas and can be used to differentiate these tumors from benign sebaceous neoplasms, as well as SCC and BCC.¹⁴ While EMA and adipophilin may have high sensitivity for sebaceous carcinoma,²⁴ SCC may also express these proteins, thus decreasing their specificity.

Figure 30-12. Sebaceous carcinoma (40×). (A) MLH1. (B) PMS2. (Used with permission from Eva Hurst, MD).

Atypical fibroxanthoma

AFX is an uncommon, superficial fibrohistiocytic tumor with an unknown exact incidence, but in one study made up 0.24% of skin cancers treated with MMS.⁴⁹ These tumors are most commonly found on the scalp (Fig. 30-13), face, and neck of elderly Caucasian men.⁵⁰ Risk factors include UV exposure, radiation therapy, and immune dysregulation.⁵¹ Histopathologically, AFX most commonly appears as pleomorphic spindle, epithelioid, and multinucleated giant cells with numerous mitotic figures and nuclear pleomorphism (Fig. 30-14).^{50,52}

Figure 30-13. Atypical fibroxanthoma presenting as a large red nodule on the frontal scalp. (Used with permission from S. Tyler Hollmig, MD).

Figure 30-14. Atypical fibroxanthoma. (A) Hematoxylin and eosin staining shows pleomorphic spindle and epithelioid cells with giant cells (200×). (B) Strong and diffuse staining with CD10 (40×). (Used with permission from S. Tyler Hollmig, MD).

Despite these malignant features and its consideration as a pleomorphic dermal neoplasm, AFX is characterized by indolent clinical behavior and rare metastasis.^{50–53} This is in contrast to undifferentiated pleomorphic sarcoma (UPS) which has a higher rate of metastasis and poor outcomes. AFX remains a diagnosis of exclusion and, unfortunately, does not have any concrete discriminatory histologic or immunohistochemical features to differentiate it from UPS.⁵³ Certain features, including larger tumor size (>2 cm), tumor necrosis, increased depth with tumor involving subcutaneous tissue and fascia, and vascular or neural involvement, may be more suggestive of UPS.^{54–56} Given the similarities and differences, AFX is viewed by some to be a superficial variant of UPS.⁵⁷ Adding to the confusion is the use of the term pleomorphic dermal sarcoma (PDS) in the literature, and the replacement of the old term malignant fibrous histiocytoma (MFH) with UPS. It should be noted that UPS, PDS, and MFH are synonymous, with the term UPS now being preferred.

WLE with 2-cm margins is necessary to clear 96.6% of tumors, leading to an increase in the use of MMS in the treatment of AFX.⁵⁷ Recurrence rates following WLE have been reported to range from 2% to 21%, while those following MMS range from 0 to 6.9%.^{57,58} In a study of 2960 patients, there was no significant difference in the recurrence and survival rates following WLE versus MMS.⁵⁹

It can be difficult to distinguish AFX from other spindle-cell neoplasms including spindle-cell SCC and melanoma, making immunostains particularly

helpful in the initial diagnosis. In an extensive review of AFX cases, 90% had negative staining for cytokeratins, S100, desmin, and HMB-45.⁵⁹ CD10 has been described as a specific stain for AFX (Fig. 30-14). However, some SCCs can also have strong CD10 staining. AFX can be differentiated from spindle-cell SCC as the latter will be positive for cytokeratins and p63.¹⁶ Negative CD34 and S100 staining in AFX can help differentiate them from DFSP and melanoma, respectively.

Merkel cell carcinoma

MCC is a rare, aggressive cutaneous neoplasm most commonly occurring on the head and neck of elderly Caucasian individuals (Fig. 30-15). Histopathologically, MCC is composed of small blue cells in sheets, nests, or in a trabecular array (Fig. 30-16). MCC can exhibit extensive vertical growth extending to the muscle or fascia, making complete excision with WLE difficult, with recurrence rates of 32% to 50% reported.⁶⁰ As with other rare tumors, recurrence rates with MMS are lower with rates of 0% to 5% reported.^{40,60} Given its radiosensitivity, adjuvant radiation therapy following MMS is a consideration.⁶⁰ Additionally, due to the high rate of metastasis, sentinel lymph node biopsy may be performed in patients without clinical or radiological evidence of nodal disease.⁶¹ A defect to lesion size ratio of 4.5 has been reported.⁴⁰

Figure 30-15. Merkel cell carcinoma presenting as a red papule on the right ala.

Figure 30-16. Merkel cell carcinoma. (A) Hematoxylin and eosin demonstrating small atypical blue cells that are primarily nested (40×). (B) “Salt and pepper” chromatin and atypical cells (hematoxylin

and eosin, 400×). (C) CK20 labeling carcinoma in a characteristic perinuclear dot pattern (400×).

Immunostaining with CK20 is often used to confirm the diagnosis of MCC.¹⁴ CK20 has a characteristic “dot-like” perinuclear staining pattern (Fig. 30-16). A similar staining pattern is seen with MNF116.²¹ Synaptophysin can be used for confirmation in cases that do not have this characteristic staining pattern.⁶² Because MCC is typically easily visualized on frozen section, immunostains during MMS tend to be unnecessary.⁶⁰

Atypical intradermal smooth muscle neoplasms (cutaneous leiomyosarcoma)

Atypical intradermal smooth muscle neoplasms (AISMN), also known as cutaneous leiomyosarcoma (LMS), are rare soft-tissue malignancies, with approximately 400 cases reported in the literature.⁶³ AISMN arises from the arrector pili muscle, while subcutaneous LMS arises from smooth muscle of the blood vessels in the subcutaneous tissue. Both are found most commonly on the extremities, but can occur elsewhere including on the face (Fig. 30-17).⁶⁴ Histopathologically, AISMN and subcutaneous LMS are characterized by hypercellular, intertwined muscle fascicles with variable mitoses (Fig. 30-18). AISMN can be aggressive, but has a lower rate of metastasis than subcutaneous LMS.⁶⁴ For some, the term AISMN has supplanted cutaneous LMS in the nomenclature, as neoplasms confined to the dermis have been found to have a very low rate of metastasis and thus should not be referred to as a sarcoma.^{65,66} However, others feel that although AISMN does recur and metastasize less frequently than its deeper counterparts, it has been implicated in causing death, and thus both should be referred to as LMS.⁶⁷

Figure 30-17. Atypical intradermal smooth muscle neoplasm presenting as an erythematous keratotic papule on the right lower vermilion and cutaneous lip.

Figure 30-18. Atypical intradermal smooth muscle neoplasm. Hematoxylin and eosin stain shows an atypical spindle-cell proliferation. (A) 20×. (B) 200×.

The standard of care for AISMN has been WLE, although no consensus has been made regarding the most appropriate surgical margins.⁶⁸ Recurrence rates are the highest in cases where less than a 1-cm margin is taken, and have been reported to be as high as 67%.^{64,65} Positive margin status may be the strongest predictor of recurrence.⁶⁶ MMS is being used more frequently in the treatment of LMS, with a recurrence rate of approximately 5%.⁶⁴

AISMN and subcutaneous LMS have a histologic appearance similar to other spindle-cell neoplasms, and immunostains are often necessary to make the diagnosis. These tumors show positive staining for smooth muscle actin (Fig. 30-19) with approximately 60% of tumors also staining positively for desmin.⁶⁹ CD34, S100, and CK5/6 are negative helping to distinguish AISMN and subcutaneous LMS from other spindle-cell tumors.⁶⁶ One case series showed a loss of phosphatase and tensin homolog (PTEN) staining in the majority of cases examined, possibly suggesting that there is a loss of PTEN expression during the development of AISMN.⁶⁶

Figure 30-19. Atypical intradermal smooth muscle neoplasm staining with smooth muscle actin (200×).

Eccrine porocarcinoma

Eccrine porocarcinoma (EPC), also known as malignant eccrine poroma, is a rare cutaneous tumor arising from the acrosyringium, the intraepidermal portion of the eccrine duct. EPC represent 0.005% of all malignant epithelial neoplasms.⁷⁰ Initially, EPC is a slow-growing lesion, but then enters a proliferative, vertical growth phase with a propensity to metastasize to regional nodes. Histopathologically, EPC is characterized by intraepidermal clusters of small, basaloid malignant cells (Fig. 30-20). Dermal invasion occurs, with broad anastomosing columns of tumor cells penetrating to varying levels of the dermis.⁷¹ Foci of squamous differentiation and melanin pigment may be present, but the presence of ductal structures can be helpful in making the diagnosis. Pagetoid spread is not a feature of EPC. Cells are rich in glycogen and thus appear clear, and are periodic acid-Schiff positive and diastase labile.⁷¹ WLE has been associated with recurrence rates of 20%, and rates of distant metastasis and death of approximately 11%.⁷² MMS has been shown to have lower rates of recurrence, and thus may offer superior outcomes compared to WLE.^{73,74}

Figure 30-20. Eccrine porocarcinoma. (A) Marked hyperplasia of the epidermis with intraepidermal clusters of pleomorphic cells and large ducts (H&E, 40×). (B) Small, poroid cells with prominent mitotic and apoptotic small ductules (H&E, 400×).

Distinguishing EPC from other entities with similar histopathological findings such as Bowen's disease, EMPD, and melanoma in situ, can be difficult, and immunostains may be necessary. EPC stains positively for CEA and EMA.⁷¹ CD117 (c-kit) may also be positive in EPC and help in the

differentiation from SCC, most of which stain negatively for CD117.⁷⁵ EPC may also stain with adipophilin.³⁵

Dermatofibrosarcoma Protuberans

A 39-year-old male was seen in the outpatient dermatology clinic for a “lump” present in his scalp for 1 month (Fig. 30-21). The clinical differential diagnosis included a pilar cyst versus lipoma. A punch biopsy was performed and demonstrated a proliferation of wavy and spindle-shaped cells arranged in short fascicles with focal arrangement in a storiform pattern. The cells infiltrated the fat in parallel bands and sometimes in a “honey-comb” pattern. The lesional cells demonstrated immunoreactivity with CD34 and did not label with factor XIIIa or S-100. The findings were consistent with a DFSP.

Figure 30-21. Dermatofibrosarcoma protuberans presenting as a subcutaneous nodule on the posterior scalp.

The patient was referred to the dermatologic surgery service and MMS was recommended. The initial clinical lesion was 3.0 cm × 2.2 cm. After

five stages of MMS, there continued to be positive lateral and deep margins with a defect of 8.0 cm × 6.5 cm. Due to approaching maximum lidocaine dose, patient fatigue, and anxiety, it was decided to resume surgery the following day where an additional 2-cm margin was resected along with deep galeal and periosteal tissue which was submitted for permanent sections (Fig. 30-22). Permanent sections processed en face failed to reveal tumor at the margins. The defect was reconstructed in the operating room with multiple rotation flaps. The patient remains tumor free 3.5 years after initial presentation.

Figure 30-22. Mohs map and resection of final 2-cm margin of a large dermatofibrosarcoma protuberans on the scalp. Margin, galea, and periosteum submitted for permanent sections.

This case exemplifies a multidisciplinary approach and use of all the tools at hand to clear these tumors. MMS is a tissue-sparing procedure and was the appropriate choice in this situation even given the positive

margins and need for later resection. An initial excision with as much as 2- to 3-cm margins still would have resulted in positive margins and the need for further resection. The tumor ultimately required a greater than 7-cm margin for tumor clearance (Fig. 30-23).

Figure 30-23. Dermatofibrosarcoma protuberans. (A) Preoperative photograph of Mohs site. (B) Postoperative defect.

The use of CD34 stains on frozen sections is fraught with difficulty. The CD34 stain is a difficult stain to interpret under the best of circumstances on paraffin-embedded tissue. CD34 labels endothelial cells and has a tendency to nonspecifically stain soft tissue. It is not recommended as a stain for frozen section diagnostic pathology. The cells of DFSP are usually readily identified in tissue without the need for an immunohistochemical stain. The immunohistochemical stain is most valuable in making the diagnosis or in situations where the Mohs surgeon is not certain regarding the margins and needs to submit paraffin embedded tissue for confirmation.

It is crucial to perform the correct surgery the first time. These cases can be very challenging, as patients that are partially resected or those that are resected and closed with positive margins may be difficult to treat. In these cases, slide interpretation is fraught with problems, and CD34 immunohistochemical staining is very challenging given the inflammatory milieu and numerous other inflammatory cells in the tissue.

Periosteum can be resected with the overlying tissue or by itself if there is a positive margin noted on the periosteal tissue. It is preferable from a reconstructive standpoint if periosteum is not sacrificed, and it

should be spared if possible. It may be ideal to submit periosteal tissue to the pathology lab. A detailed map is made and the periosteum is usually bread-loafed after fixation. Other Mohs surgeons prefer to process this tissue with frozen sections. This is delicate tissue and requires proper handling in either circumstance.

Squamous Cell Carcinoma with Perineural Invasion

An 86-year-old male presented with a pruritic nonpainful lesion in the ear that, per the patient, had been present for several months ([Fig. 30-24](#)). On examination, there was a 2-cm ulcerated erythematous plaque in the right conchal bowl. MMS was performed and revealed poorly differentiated SCC with prominent perineural invasion. Examination of the debulk tissue specimen showed perineural SCC involvement of a small 0.04-mm-diameter nerve. AE1/AE3 staining was used to highlight tumor on the first two stages ([Fig. 30-25](#)). Four stages were required to clear the tumor, resulting in a defect spanning the conchal bowl ([Fig. 30-26](#)).

Figure 30-24. Invasive squamous cell carcinoma of the right conchal cavity.

Figure 30-26. Defect after four stages of Mohs micrographic surgery for an invasive squamous cell carcinoma.

This case exemplifies the usefulness of cytokeratin stains in highly inflamed tissue to detect occult SCC. Heavy inflammation, particularly around nerves, is very concerning in patients with large and/or poorly differentiated SCC. This case demonstrates the ability to use frozen section immunohistochemistry to detect these occult invasive carcinomas. For surgeons who lack the ability to perform these stains intraoperatively, they can be used in formalin-fixed paraffin-embedded tissue. This particular tumor can be successfully treated in a number of different ways, with or without frozen section immunohistochemistry, but what is needed is a working relationship with a pathology laboratory and dermatopathologist if the surgeon elects to send this tissue for permanent section pathology.

CONCLUSIONS

While used in only select cases, immunohistochemical staining has become an important part of the dermatologic surgeon's armamentarium. A thorough understanding of the varieties of available stains and their potential application is critical when contemplating treating rarer tumors with MMS. By combining meticulous thin frozen sections with an array of immunostains, the recurrence rate of difficult tumors may be significantly decreased, leading to clinically significant implications for the patient.

CHAPTER 31 Mohs and Staged Geometric Excision for Lentigo Maligna

Glen M. Bowen

SUMMARY

- Lentigo maligna and lentigo maligna melanoma are very common in the elderly population.
- Surgical approaches include Mohs surgery (relying heavily on immunohistochemical staining) and staged excisions.

- Radiation therapy is particularly popular outside of the United States, while imiquimod may be better used as a neoadjuvant approach rather than monotherapy except in select patients.
- The large margins often needed mean that surgery may have significant associated morbidity.

Beginner Tips

- Closing the excisional biopsy with a single or double purse string shrinks the size of the defect down to its smallest possible surface area.
- After taking a stage for LM, a fascial plication suture and/or an intradermal traction suture can be left in place while the tissue is being processed. This allows the skin to relax along the RSTLs and facilitates the ease of closure when negative histologic margins have been confirmed.

Expert Tips

- The nuclear stains MiTF and SOX10 are less sensitive than MART-1/Melan-A, but are more specific as they do not stain dendritic processes or keratinocytes, and enable a much more accurate melanocyte density count.

Don't Forget!

- The application of topical imiquimod 5% in the neoadjuvant setting for 5 days weekly for 2 to 3 months allows for the removal of over 90% of LM lesions with a conservative 2-mm margin compared to the average requirement of a 7.1-mm margin for cases of LM untreated with topical imiquimod.
- The negative control allows for subtraction of the atypical junctional melanocytic hyperplasia common to chronically sun-exposed skin from the LM surgical margins and increased accuracy of concordance rates between dermatopathologists assessing surgical margins of LM specimens.

Pitfalls and Cautions

- SOX10 commonly stains eccrine cells and regenerating Schwann cells in scar tissue, so care must be taken to not falsely record dermal invasion in those cases.

Patient Education Points

- RT provides a gentler approach with better cosmetic outcomes, but may have a somewhat higher local recurrence rate and morbidity.
- The low mortality risk of treated LM and its prevalence in the elderly population means that therapy should always be tailored to the individual patient and an extensive discussion regarding risks, benefits, and alternatives should always be undertaken.

Billing Pearls

- Coding for true Mohs for LM utilizes the 17311-2 series and 17313-4 series used for tumors of the head/neck/hands/feet/genitalia and all other areas, respectively.
- Billing for immunohistochemical stains is in addition to standard Mohs layer billing, and is generally billed on a per-specimen basis with code 88342 for the first antibody followed by 88341 for each additional antibody. If multiple separately identifiable antibodies are applied to the slide, use one unit of 88344.

CHAPTER 31 Mohs and Staged Geometric Excision for Lentigo Maligna

INTRODUCTION

Melanoma is divided into several categories based on clinical and histologic features, including superficial spreading, nodular, lentigo maligna melanoma (LMM), and acral lentiginous melanoma. Ocular melanoma is a distinct entity with its own unique clinical and genetic features.

Lentigo maligna (LM), which is an in situ tumor,¹ and LMM, an invasive progression from LM, share some features with other melanoma subtypes, but also display unique characteristics that influence both diagnostic criteria and treatment planning. Compared with the other melanoma subtypes, LM/LMM also has the highest rates of local recurrences,^{2,3} and has a strong predilection for sites of chronic sun exposure, most commonly on the head and neck,^{1,4-7} and tends to occur in a relatively older patient population, with a peak incidence in the seventh to eighth decades.^{8,9} By contrast, superficial spreading and nodular melanomas occur at an earlier age and are distributed less commonly in sites of chronic sun exposure. Acral lentiginous/mucosal melanomas are subdivided into three subcategories, including those occurring on the palms and soles, as part of the nail apparatus, and in mucosal sites.¹⁰⁻¹³

LM is associated with unique diagnostic and treatment challenges as a consequence of its location in cosmetically sensitive areas of the head and

neck. With regards to diagnostic challenges, Caucasian skin often shows melanocytic hyperplasia (often with varying degrees of cellular atypia) at the dermoepidermal junction in chronically sun-exposed sites, and LM arises in this background.^{14–16} Distinguishing between the histologic border of where LM stops and background atypical junctional melanocytic hyperplasia begins in a background of sun-damaged skin can be challenging, since sharp lines of demarcation often do not exist,^{17,18} and there is no currently available genetic marker to distinguish between a malignant melanocyte and a nonmalignant melanocyte. Therefore, relatively large surgical margins are needed to confidently verify negative histologic margins.¹⁹ With regards to treatment challenges, the morbidity of the surgical treatment of LM needs to be balanced by the associated risk of an LM progressing to LMM, while nonsurgical treatment approaches must be carefully weighed against surgical options in terms of efficacy.

A wide range of estimates have been published regarding the natural history of an untreated LM, that is, the percent of LM that will progress to LMM, with some as low as 5%²⁰ and some as high as 50%.²¹ Risk assessment is further complicated by the relatively common occurrence of occult invasive melanoma with LM. Two separate manuscripts examining staged excision for LM coincidentally observed unsuspected invasion in 16% of excised LM specimens.^{19,22} A number of other studies have been published on the rate of upgrading LM to LMM when definitive surgery is performed, with rates ranging from 5% to 29%,^{17,19,22–28} and an average incidence of invasion calculated to be about 19% based on published studies to date.¹⁴

Because LMM behaves as aggressively as other subtypes of melanoma when adjusted for Breslow depth,²⁹ it is critically important that the physician properly stages the melanoma prior to definitive treatment.

When choosing a treatment approach to the patient with LM, the risk–benefit ratio must be taken into account. Factoring heavily in that calculation is the patient’s age, performance status, and cosmetic expectations.

CLINICAL PRESENTATION

It is difficult to pinpoint the exact incidence of LM in the United States since it is often not captured as a distinct diagnosis in tumor registries. An estimate has been made of 13.7 per 100,000 person-years but this is most certainly an underestimate.³⁰ The rates of LM are predicted to increase in most developed countries as life expectancy increases over time.³⁰⁻³² LM occurs most commonly in Caucasians with a predilection for chronically sun-exposed areas in a relatively older population.

The distinction between a benign lentigo (solar or simple lentigo) and LM on clinical grounds is generally a function of the LM being much larger and often with nonuniform coloring, with areas of varying pigment intensity on the brown aspect of the color spectrum (Fig. 31-1). As such, LM will generally demonstrate the “ugly duckling” sign.³³ One might imagine a Gaussian bell curve of pigmented lesions on a given patient that cluster toward a mean of shared features, with LM being a standard deviation apart in its gestalt appearance.

A

B

Figure 31-1. A. LM on the right forearm. B. Close-up view. Note the disparate color tones when compared to the surrounding lentiginos.

BIOPSY TECHNIQUES

The diagnosis of LM cannot be made reliably on clinical grounds alone. Since LM tends to be larger in terms of surface area compared to other subtypes of melanoma, sampling error may be a problem when incisional biopsies represent only a fraction of a much larger tumor.³⁴ Multiple punch or shave biopsies may be performed to sample the areas of greatest suspicion—those with the greatest color variations compared to the overall color tone of the lesion.³⁴ These areas chosen for *incisional biopsy* may be areas where the pigment is the darkest and also sometimes lighter or erythematous areas if regression is suspected, which may appear bluish gray or hypopigmented. As an alternative to multiple incisional biopsies, a long thin fusiform biopsy can be easily performed in most cases and closed with a running absorbable suture with minimal cosmetic penalty (Fig. 31-2). For very large tumors, two fusiform biopsies can be performed at 90-degree angles yielding a cruciate pattern that helps to reduce the risk of sampling error (Fig. 31-3).

Figure 31-2. Fusiform biopsy for LM in an attempt to rule out invasion. In this case, no invasion was seen and the patient was subsequently treated with radiotherapy.

Figure 31-3. Two long, thin fusiform biopsies performed on the site of a large basal cell carcinoma treated with oral vismodegib. The biopsies were performed to screen for any areas of residual tumor. The technique may also be applied to cases of clinically large LM where there is suspicion for invasion.

The best evidence for determining whether a presumed LM specimen harbors an invasive component is by histologic review of the entire specimen, that is, an *excisional biopsy* where all visible tumor is removed.

Most patients referred for surgical treatment of LM were diagnosed by incisional biopsy, and abundant residual clinical tumor remains on physical examination. In these cases, an excisional biopsy may uncover an invasive melanoma in 19% of cases, even when the clinical suspicion for invasion is low.¹⁴ Excisional biopsies can often be closed with an intradermal purse-string suture in either a single or double configuration depending on the size and shape of the lesion (Fig. 31-4).³⁵⁻³⁸ Once the purse string has had time to heal, the definitive surgery can take place around the contracted margins of the excisional biopsy scar and reduce overall surgical morbidity.

Figure 31-4. Single and double purse-string sutures. **A.** Single purse-string suture: An absorbable intradermal suture is placed 360 degrees around the defect and drawn closed. **B.** Double purse-string suture: An intradermal suture halves the defect by being placed in the center. The two smaller circles are closed with individual purse strings.

HISTOLOGY

The essential histologic feature of LM is an increase in junctional melanocytes with varying degrees of cellular atypia superimposed on a background of the stigmata of chronic sun exposure such as solar elastosis and epidermal atrophy. Many histologic features associated with LM have been described as focal findings in chronically sun-damaged skin uninvolved by LM.³⁹ It is unclear when junctional melanocytic hyperplasia on sun-damaged skin is distinguished from an LM precursor or LM, and this leads to a high rate of diagnostic disagreement among dermatopathologists.²⁹ Some dermatopathologists will evaluate junctional melanocyte atypia with grades that range from mild, moderate, to severe, the latter beginning to fuse with the entity of LM. Other terminology used to convey the concept of an LM precursor includes “evolving melanoma in situ” and “atypical junctional melanocytic hyperplasia,” though these terms are neither well defined nor uniformly utilized by dermatopathologists.

Given the lack of a specific tumor antigen that can be identified on a malignant melanocyte, the question must be asked as to how the histologic diagnosis of LM can be most accurately and reproducibly made. The histologic criteria for MIS have been described by Higgins et al. as follows: (1) poor circumscription; (2) asymmetry; (3) a predominance of individual melanocytes over nests with (a) confluent growth along the dermoepidermal junction, (b) effacement of rete ridges, and (c) pagetoid scatter; (4) nests of atypical melanocytes with (a) confluence, (b) variability in shape and size, (c) consumption of epidermis; (5) haphazard distribution; and (6) involvement of adnexal epithelium.¹⁴ The authors point out that MIS can be subdivided into LM, superficial spreading, acral lentiginous, and mucosal subtypes and within those, LM typically demonstrates effacement of the rete ridges and single cells predominating over nests of cells with varying degrees of pagetoid scatter.¹⁴

Unfortunately, many of the histologic criteria for LM can be seen in melanocytic hyperplasia in sun-damaged skin in negative control specimens (samples of skin far removed from the LM surgical site but in areas of comparable photodamage). Approximately 30% of negative control specimens have been reported to demonstrate histologic features common to LM.³⁹ In a study by A. R. Bowen et al., the only histologic feature that was

statistically significant in making a distinction between LM and the negative control was the relative disparities in melanocyte density (LM with 82.9 $\pm$ 23 cells per 400 $\times$ field vs. 32 $\pm$ 9 cells per 400 $\times$ field in the negative control).³⁹ A study of patients with LM treated with topical imiquimod showed a higher density of melanocytes in biopsies of the LM lesions that recurred compared to LM lesions that did not recur, (57.17 melanocytes per millimeters of epidermis vs. 34.12 melanocytes per millimeters of epidermis, respectively).⁴⁰ An additional study from Scotland compared LM cases that recurred following surgery to those that did not and also found that melanocyte density was strongly predictive of recurrence risk ($p = 0.0001$), with recurrence risk divided into three categories: low risk: 0 to 20 melanocytes/400 $\times$, intermediate risk: 21 to 30 melanocytes/400 $\times$, and high risk: >31 melanocytes/400 $\times$.⁴¹ The melanocyte cell count in LM is much more reproducible between pathologists than are assessments of degrees of other histologic markers such as pagetoid spread, extent of adnexal extension, and melanocyte atypia.

The degree of uncertainty in the baseline diagnosis of LM is mirrored in the downstream assessment of surgical margins when LM is excised. Thus determining the boundary between the surgical margin of LM and surrounding melanocytic hyperplasia common to chronically sun-exposed skin in Caucasians is challenging.^{2,15–18} Concerning the diagnosis of LM, two separate studies have demonstrated very clearly that concordance rates between expert dermatopathologists in diagnosing all types of melanoma is moderate at the best.^{42,43} With regards to the surgical margins of staged excisions specifically for the LM variant of melanoma, Florell et al. distributed paraffin-embedded permanent section of en face excisional margins of LM to five dermatopathologists who were asked if the margins were “positive” and required further surgery or “negative” and did not; again, concordance rates were only moderate.²⁹ Equally disturbing were the unimpressive intraobserver concordance rates when the dermatopathologist examined the same slide on two different occasions.²⁹ In this same study, despite the complexity of establishing consistency in the diagnosis of surgical margins of LM, the submission of a negative control improved concordance rates between dermatopathologists with statistical significance.²⁹

Reports on the melanocyte densities for LM/LMM¹⁴ range from 37.8 to 112 melanocytes at 400 $\times$ magnification^{39,41,44–47} compared to a range of 3.99

to 34.9 in negative controls.^{16,17,39,44,45,47–49} Problematically, the low range for LM/LMM (37.8 cells/400x) is very close to the high range for a negative control (34.9 cells/400x). For this reason, establishing a negative control for each specific patient maximizes the accuracy of comparative melanocyte density counts but does not eliminate the ambiguity. Being able to make a comparison of melanocyte density between surgical margins of LM and chronically sun-exposed skin at baseline is critically important in increasing the accuracy of the interpretation of the surgical margins of LM.¹⁷

GENETICS

There are a variety of genetic aberrations that are observed in melanoma and tend to cluster by site of occurrence. These general groupings include areas of chronic sun exposure (LM/LMM), sites of intermittent exposure such as the torso and proximal extremities (superficial spreading and nodular subtypes), and those that occur on relatively sun-protected areas including the acral and mucosal melanoma variants. LM/LMM is distributed in a similar way to the nonmelanoma skin cancers, particularly basal cell carcinoma (BCC) and squamous cell carcinoma (SCC). LM/LMM has an extraordinarily high number of somatic mutations, in the range of 100,000.⁵⁰ In contrast to melanomas in areas of intermittent sun exposure, LM/LMM has less frequent BRAF mutations, and when present, have BRAF V600K variants more frequently than the BRAF V600E mutations more common in superficial spreading and nodular melanoma subtypes.^{51–53} LM/LMM also has inactivating mutations in NF1 (30%),⁵² increased copy number of CCND1 (20%),^{54,55} and activating mutations in KIT (10%).⁵⁶ The pattern of chromosomal abnormalities seen in comparative genomic hybridization studies comparing LM/LMM to other melanoma subtypes is also different.⁵⁴ LM occurs in a field of genetic aberrations as a consequence of both ultraviolet light directly on DNA as well as secondary effects of DNA damage due to singlet oxygen formation. This “field” where many various mutations occur over a lifetime may explain why LM occurs in a relatively older population than other melanoma subtypes⁵⁷ as well as having a higher local recurrence rate and a wider surgical margin requirement to confirm negative histologic margins. The “field-cell” phenomenon has been

demonstrated in acral and mucosal melanomas where in situ hybridization on cells surrounding the tumor in clinically normal-appearing skin has revealed histologically banal melanocytes but are found to harbor gene amplifications identical to the melanoma cells.^{58,59} It is not known if such a field effect exists in LM/LMM, though Bastian and colleagues believe are likely given the range of genetic abnormalities in sites of chronic sun exposure, the lentiginous pattern of growth that LM/LMM subtypes of melanoma share with acral and mucosal melanomas, and the tendency for local persistence.⁵⁹

TREATMENT

Therapeutic approaches to LM vary widely from institution to institution and from country to country.

SURGERY

While surgical treatment is generally considered the most effective treatment for LM/LMM, there is only limited long-term follow-up data on any LM/LMM treatment. Moreover, surgery is often associated with morbidity given the large surgical margins required to confirm complete removal of the LM,⁶⁰ especially as given the larger clinical surface area of LM, a proportionately larger margin of resection is required to confirm negative margins.⁶¹

The observed average time for a local recurrence in LM has been reported at 5.9 years.⁶² To date, there are two sequential studies from one private practice group that have follow-up data regarding staged excisions for LM/LMM longer than 5 years, with recurrence rates of 7.3% (95-month mean follow-up)⁶³ and 5.9% (138-month mean follow-up).⁶⁴ Because all other studies reporting recurrence rates have follow-up times less than 5.9 years, it is not valid to draw conclusions about the reported data on recurrence rates which range from 0% to 10%.^{19,23,26,27,61,63,65–77} There is a strong bias in the United States toward the surgical treatment of LM rather than nonsurgical techniques. Specific requirements for surgical margins for LM/LMM have not been rigorously defined.⁷⁸ It is abundantly clear from the published literature that the standard recommendations of a 5-mm surgical

margin for melanoma in situ from a consensus conference sponsored by the National Institutes of Health published in 1992⁷⁹ is frequently inadequate for the LM variant of MIS.^{19,22,75,80,81} LM is characterized by histologic borders that often extend far beyond what the clinically visible tumor margins appear to be under Wood's lamp examination.⁸² On average, 7.1 mm are required to achieve negative histologic margins for LM, and 10.3 mm for LMM.¹⁹ It has been recommended to take 9 mm^{80,83} or even >10-mm margins⁸⁴ when a wide local excision (WLE) is being performed in lieu of a staged excision for LM, with recommendations to confirm negative histologic margins prior to repair. The 9-mm recommendation is for *any form* of MIS although some dispute this and believe that there is a distinction in margin requirements for MIS in intermittently sun-exposed sites (SSMIS) or MIS in chronically sun-exposed sites (LM).^{60,78,85}

The National Comprehensive Cancer Network is a consortium of academic cancer centers across the United States and makes an annual report on treatment algorithms for melanoma and other cancers. The recommended treatment for LM is surgery with a surgical margin of 0.5 to 1.0 cm with a footnote comment that reads: "For large melanoma in situ (MIS) lentigo maligna type, surgical margins >0.5 cm may be necessary to achieve histologically negative margins; techniques for more exhaustive histologic assessment of margins should be considered. For selected patients with positive margins after optimal surgery, consider topical imiquimod (for patients with MIS) or radiotherapy (RT) (category 2B)."⁸⁶ Category 2B connotes a majority opinion among member institutions but without a unanimous consensus.

Over the years, there have been a dizzying number of published papers advocating a wide variety of surgical and histologic processing techniques. In a review of MIS of all subtypes, Higgins et al. chose to categorize surgical techniques into three categories: WLEs, staged excisions (as defined by the use of paraffin-embedded permanent sections), and Mohs micrographic surgery (MMS), defined as using frozen sections (often augmented by immunohistochemical staining).¹⁴

WIDE LOCAL EXCISIONS

The main issue with WLE for LM/LMM is selecting a margin that balances the probability that the LM will actually be removed against the morbidity of removing more tissue than is necessary in cosmetically sensitive sites. Only 42% of LM will be clear with a 5-mm margin using WLE.²² Second, an average of 7.1 mm is required to achieve negative histologic margins for LM (and 10.3 mm for LMM).¹⁹ Therefore, a 9- to 10-mm margin for WLE should be considered, which yields an excisional diameter of 2 cm not including the actual size of the original tumor.^{80,84} For this reason, WLE is associated with the greatest surgical morbidity compared to staged surgical techniques that more precisely restrain the surgical margins to the actual two-dimensional shape of the tumor footprint.

STAGED EXCISIONS

Staged excisions can be performed in a number of ways and may be defined by the manner in which the LM is removed and how it is sectioned and processed for histologic evaluation. The categories that utilize en face vertical sections are “bread-loaf” sectioning, “picture-frame” sectioning, “contour” sectioning, and “radial” sectioning. The technique that uses en face horizontal sectioning is MMS.

VERTICAL SECTIONING TECHNIQUES

Bread-loaf sectioning

The technique using vertical sections cut from parallel strips of tissue along the length of the resected specimen is referred to as “bread-loaf” sectioning. The purported advantage of bread-loaf sectioning is to allow the pathologist a view of the transition of the tumor from the inside central margin as it radiates out toward the outer edge of the tumor. Thus the yolk of a fried egg represents the residual melanoma and the surrounding egg white the tumor-free zone (Fig. 31-5). The limitation of bread-loaf sectioning is that a relatively small percentage of the three-dimensional tumor is actually visualized microscopically.⁸⁷ A study by Kimyadi-Asadi et al. reviewed cases of MIS excised with frozen sections bread-loafed at sections in 1-,

2-,4-, and 10-mm intervals and found that there was a positive margin rate of 58%, 37%, 19%, and 7%, respectively.⁸⁸ The authors concluded that bread-loaf sections would have to be cut as thin as 0.1-mm intervals in order to view close to 100% of the surgical margins.⁸⁸

EN FACE VERTICAL SECTIONING TECHNIQUES

“Picture-frame” sectioning

“En face” implies that the specimen is sectioned with its “face” at its peripheral margin. Johnson et al.⁶⁶ described a technique of removing a strip of tissue in the shape of a square or rectangle around the visible LM much like the frame around a picture (Fig. 31-6). The four sides of removed tissue are submitted for permanent sections cut en face with vertical sections from the outer edge toward the center of the specimen (as opposed to the horizontal sectioning used in MMS) with routine staining with H&E. The patient is brought back on subsequent visits for additional stages as needed and then ultimately for the reconstruction once negative margins had been confirmed. It is possible to process the specimens as frozen sections but Johnson and colleagues prefer formalin-fixed paraffin-embedded sections, which is the preference of many dermatopathologists.

Figure 31-6. The "picture-framing" technique.

The immediate advantage of an en face vertical sectioning technique over bread-loaf sectioning is the closer approximation to a 100% evaluation of the 360-degree excised surgical margin. A study comparing bread-loaf sectioning (156 patients with a median follow-up of 81 months) versus en face vertical sectioning (136 patients with a median follow-up of 44 months) reported a recurrence rate of 6.4% versus 0.7%, respectively.⁸⁹ A second study compared bread-loaf sectioning versus en face sectioning in the surgical excisions of acral lentiginous melanoma. This study included 241 patients with a median follow-up of 41 months and compared survival rates which were 81% in the en face vertical section group versus 63% in the

transverse section group.⁹⁰ The authors refer to en face vertical sectioning as “3-D” and noted a reduction of excision margins by two-thirds, lower local recurrence rates, and longer survival times when compared to bread-loaf section analysis of tumor margins.⁹⁰

The limitations of the “square” or “picture-framing” technique are: (1) The patient must return to clinic on subsequent days for either reconstruction or another stage of surgery, which becomes increasingly onerous if multiple surgical stages are required. (2) The central portion of the tumor is not submitted until negative-perimeter margins have been evaluated. This leads to the possibility that the patient would undergo reconstruction before it was known if invasion was present in potentially 19% of cases.¹⁴ This could be problematic for T1b tumors or higher (>1.0 cm, or mitotic figures >1/mm, or ulceration) where a sentinel lymph node biopsy could be considered. Additionally, the excision margins for invasive melanoma call for their depth to include the adipose layer to fascia.⁸⁶ Some surgeons argue against the utility of a sentinel lymph node biopsy in melanoma.^{91–93} However, there are two approved adjuvant agents available for patients with positive lymph nodes (interferon-alpha2b approved in 1995⁹⁴ and ipilimumab approved in 2015),^{95,96} as well as several clinical trials available to patients with positive sentinel nodes. Without interrogation of the sentinel lymph nodes, these patients are ineligible for adjuvant clinical therapies they may have otherwise be anxious to try. (3) The potential for miscommunication between the dermatopathologist and the surgeon regarding the specific locations of residual tumor. This potential source of error is minimized with frozen sections where the surgeon also serves as the pathologist.

Contour sectioning

A similar method was reported, called the “spaghetti technique,” which converted the square or rectangular shape to a more organic shape which more closely follows the contour of the visible LM.⁷⁷ The resultant strips of removed tissue are not necessarily straight lines as with the picture-framing method but can be laid flat and cut en face with vertical sections. This approach involves circumscribing the visible tumor with the desired margin and sectioning a 360-degree narrow band of tissue, leaving the LM in the center and then temporarily suturing the defect closed (Fig. 31-7). As with

the picture-framing technique, the residual LM is subsequently removed from the center once negative-perimeter margins have been defined. The purpose of leaving the residual LM in the center is to avoid an open wound while waiting for the results from formalin-fixed paraffin-embedded sections. With either the picture-frame or contour techniques, the surgeon has the option of suturing the 360-degree perimeter defect closed to avoid an open wound while the patient awaits the pathology report.

Figure 31-7. The "contour" technique.

The advantage of this technique over the picture-frame technique is that the excised specimen more closely follows the contour of the original tumor and removes less tissue. It shares the disadvantage that the central portion of the LM is not removed until after negative-perimeter margins have been

confirmed. This introduces the risk that invasion, if present, is not detected until after the reconstruction has been performed. Also, some advocates of picture framing may argue that by submitting polygons with distinct shapes, there is less risk for miscommunication between the dermatopathologist and the surgeon as to the exact location(s) of residual tumor. The accuracy of that communication is going to be a function of the quality of the tumor mapping by the surgeon submitting the specimens and the dermatopathologist transmitting correct sites of tumor involvement to that map.

Radial sectioning

An alternative histologic view of LM is preferred by some pathologists and Mohs surgeons and involves “radial” sectioning. In this technique, the specimen is removed and is grossed in by sectioning the tumor into radial sections similar to slices of pie wedges.²⁶ Each individual pie wedge is cut en face with vertical sections generating either frozen or formalin-fixed paraffin-embedded sections (Fig. 31-8). This technique has the advantage of allowing a view of the central portion of the LM, where (1) invasion can be ruled in or out, and (2) one can assess the diminution of the melanocyte density from the center to the outside edge of the excision, and in this sense, provides an internal “positive control” from the center of the residual tumor. The ability to see the decline in melanocyte density from the center of the LM to the outer surgical margin is the touted advantage of bread-loaf sections.

The "Radial Section" technique

Figure 31-8. The “radial section” technique.

Critics of radial sectioning point out that the width of the outside arch of each pie-wedge section prohibits viewing of a true 360-degree perimeter of the tumor margins as opposed to the view rendered with MMS, picture framing, or contouring (Fig. 31-8). Proponents of the radial technique argue that the approximation of the area under a curve is accurate if the integrals are sufficiently narrow to approximate the 360-degree perimeter margin, and that published recurrence rates are similar to those described with staged en face techniques or MMS.^{19,26} Another criticism of the radial technique is the time requirement for the grossing-in process usually involving defatting, quadrisectioning the tumor, inking the quadrants, and subdividing each quadrant into thin pie-wedge sections (Figs. 31-9 and 10). Proponents argue that the additional grossing-in time is marginal and can be delegated to a qualified histotechnologist, and that the added benefit of being able to visualize the diminution of the melanocyte density from the center to the perimeter is well worth the extra labor and time of grossing-in the specimen. When using frozen sections with immunostaining to augment H&E, this technique may be performed in a single day.

Figure 31-9. Grossing-in a radial section LM with a negative control. **A.** Excised LM from the right helical rim with a negative control. **B.** Specimen is quadrisectioned.

Figure 31-10. Mounting radial pie wedges on the cutting chucks. **A.** Each quadrant sectioned into six thin pie-wedge sections (number of pie wedges varies with the size of the tumor). **B.** Pie wedges from each quadrant mounted on chucks for en face sectioning in cryostat.

EN FACE HORIZONTAL SECTIONING TECHNIQUE

Mohs micrographic surgery

MMS involves cutting frozen tissue with en face horizontal sections. Most commonly, the central portion of the tumor containing visible signs of LM is removed as a debulking layer which is submitted in formalin for paraffin-embedded permanent sections⁹⁷ as is the case with en face vertical sectioning techniques (picture-framing and contour techniques). The removed perimeter tissue is generally sectioned in a cryostat at a thickness of 4 μ m and stained with H&E and is often augmented with immunostains. If margins are judged to be positive, additional layers are taken until negative histologic margins can be confirmed (Fig. 31-11).⁹⁷ There are numerous published

studies on MMS for LM/LMM that demonstrate its effectiveness at tissue sparing,^{27,70,72,98–100} though follow-up times are not sufficient to adequately evaluate recurrence rates.

**The Mohs micrographic surgery
“Horizontal sectioning” technique**

Figure 31-11. The Mohs micrographic surgery “horizontal sectioning” technique.

The advantages of MMS with en face horizontal sectioning on frozen tissue is that the surgery can usually be completed in 1 day and that grossing is fairly rapid. The disadvantage, as with the picture-framing and contouring techniques, is that the central LM specimen is submitted for permanent sections (and the reconstruction is performed) before the LM has been properly staged.⁸⁷ This approach has the potential to put the surgeon in an awkward position of having to explain to a patient that they have an upstaged tumor that has already been reconstructed in an average of 19%¹⁴ of cases with inadequate depth of excision to the fascia recommended for invasive melanoma.⁸⁶ Critics of this approach argue that definitive surgery is being performed prior to accurate staging of the cancer.

Another very important disadvantage to MMS and radial sections utilizing frozen tissue is the compromised ability to accurately assess cellular atypia with frozen sections.¹⁰¹ In this case, the pathologist reviewing frozen sections is reliant on pattern recognition and melanocyte density counts where it is extremely difficult to distinguish bordering melanocytic atypia in chronically sun-damaged skin.^{39,41}

Tissue processing: paraffin-embedded permanent sections versus frozen sections

Paraffin-embedded permanent sections are preferred by dermatopathologists for interpreting LM margins since the resolution allows for more accurate assessments of melanocyte/cellular atypia. The downside to permanent sections is the processing time. Because cells are comprised mostly of water and because water expands when frozen, frozen sections for LM/LMM are hampered by several artifactual perturbations. There is a tendency for

melanocytes to bloat when frozen, making them much more difficult to distinguish from surrounding basal cells/keratinocytes with H&E staining, and an assessment of individual cellular atypia is nearly impossible.^{14,44,102} This blurring of the distinctions between melanocytes and keratinocytes greatly hampers the ability of the dermatopathologist to assess cellular atypia as well as melanocyte number and distribution. In a paper entitled, “Are en face frozen sections accurate for diagnosing margin status in melanocytic lesions?” 15 dermatopathologists examined margin status of both melanoma and nonmelanoma surgical excisions by comparing en face frozen sections with paraffin-embedded permanent sections and found a discrepancy regarding margin status in 40% of cases; the authors concluded that en face frozen sections are not suitable for evaluating margin status in melanomas.¹⁰¹ Additionally, frozen sections are cut thicker than are paraffin-embedded sections which leads to crowding that can simulate the pattern of confluence seen in MIS.^{87,101–103}

Stonecipher et al. also advocated rush permanent sections over frozen sections when applying MMS to LM/LMM to improve the accuracy of interpreting melanocytic cellular atypia.¹⁰⁴ Others have argued that there is good correlation between frozen section MMS for LM/LMM with H&E staining alone compared to permanent sections,^{98,100} though Zitelli et al. who reported 90% specificity and 100% sensitivity comparing frozen sections to permanent sections using H&E staining alone have subsequently advocated immunohistochemical staining on frozen sections for LM/LMM to improve accuracy.^{44,102} Because concordance rates between dermatopathologists in interpreting staged excisions of LM with paraffin-embedded permanent sections is only moderate at best,²⁹ great caution should be used by Mohs surgeons relying on frozen sections to assess LM margins.

Slow Mohs (staged excisions with rush permanent sections)

Slow Mohs is a technique to address the shortcomings of frozen section analysis of surgical margins for LM/LM and involves rush permanent section analysis of surgical margins. This is the technique used in the descriptions of the picture frame⁶⁶ and contour techniques⁷⁷ utilizing en face vertical

sections and by some advocates of the radial technique.^{19,26} The term “Slow Mohs” is a misnomer for two reasons: (1) The Mohs surgeon is generally not the person interpreting the slides, as they are usually read by a dermatopathologist. (2) Many times the specimens are not submitted for en face horizontal sections as is done in MMS but rather with perimeter en face vertical sections (picture framing, contour, or radial techniques). In this regard, techniques that employ formalin-fixed paraffin-embedded sections are more accurately referred to as “staged excisions with rush permanent sections.” Proponents of this technique advocate greater accuracy in margin assessment, as opposed to MMS with frozen sections.⁸⁷

Frozen sections augmented with intraoperative immunohistochemical stains

Given the inherent difficulties associated with freeze artifact, there have been numerous publications on the addition of intraoperative immunohistochemistry (IHC) to frozen sections for LM/LMM as a means to circumvent the problem of decreased cellular detail and clarity when compared to permanent sections. Because cellular detail is mostly obscured with frozen sections, immunostaining may help to discriminate between the melanocytes and basal cells/keratinocytes, though it cannot distinguish between a malignant and a benign melanocyte.¹⁰⁵ In making a judgment as to whether or not the immunostained melanocytes are benign or malignant, one must rely on melanocyte density and cluster patterns to make that determination.^{39,41} Immunostains have been applied to a number of melanocytic lesions evaluated with permanent sections where there is potential for ambiguity such as melanocytic hyperplasia in chronically sun-exposed skin, desmoplastic melanoma, and pigmented actinic keratosis, to name a few.^{17,45,48,106–108}

MART-1/Melan-A

A number of manuscripts appear in the literature touting a variety of immunostains for frozen section analysis of surgical margins for LM.^{44,47,49,102,109,110} The most commonly used antibodies are MART-1

(melanoma antigen recognized by T-cells)^{111,112} or Melan-A (which recognize epitopes on the same transmembrane glycoprotein of melanocytes as does MART-1).^{113,114} They have been demonstrated to be more sensitive for the detection of melanocytes than HMB-45.¹¹²

Many clinicians have reported the successful implementation of MART-1/Melan-A immunostaining on frozen sections in MMS for LM/LMM.^{39,102,103,109,110,115} Figure 31-12 shows Mart-1 immunostaining on a radial section for LM. Although the addition of the MART-1/Melan-A immunostain can decrease the ambiguity incident to freeze artifact, there are several additional caveats to consider. MART-1/Melan-A antibodies will bind to cells that contain melanosomes which include melanocytes, but also other cells such as keratinocytes and melanophages, as well as avidly staining the dendritic processes of the melanocytes, which makes melanocyte density calculation very difficult in many cases. There have been several reports of pigmented lesions with associated lichenoid infiltrates stained with MART-1/Melan-A that were erroneously interpreted as having positive surgical margins secondary to promiscuous immunostaining that simulated MIS.^{108,116} Such reports are worrisome, since approximately 6.7% of cases of melanoma can have associated lichenoid inflammatory patterns.⁸⁷ Additionally, pigmented actinic keratoses, common in chronically sun-exposed skin can also have avid MART-1/Melan-A staining and simulate a positive surgical margin.¹¹⁷ Fixed drug eruptions have also posed a similar diagnostic dilemma with MART-1/Melan-A staining.¹¹⁸

Figure 31-12. Mart-1 immunostaining of a radial section of LM. **A.** Radial sections immunostained with Mart-1 at low power showing the termination of the LM. **B.** Higher-power view of the presumed terminus of the LM as indicated by the *red arrow*.

Because melanosomes are cytoplasmic and do not enter the nucleus, immunostains that are specific for melanocytic nuclei can help to overcome

the lack of specificity inherent in melanosome-based immunostaining. Two such antibodies are MiTF and SOX10. It has recently been observed that actual melanocytic nests can be seen in lichen planus that could simulate melanoma in situ; therefore, even the increased specificity of the nuclear stains must be viewed in the context of scenarios prone to false-positive reads of melanoma in situ.¹¹⁹

NUCLEAR IMMUNOSTAINS (MITF AND SOX10)

MiTF (microphthalmia transcription factor)

The two commercially available antibodies that bind to melanocytic nuclei are MiTF (microphthalmia transcription factor),¹²⁰ a nuclear transcription factor, and SOX10, also a transcription factor expressed in melanocytic nuclei.^{121,122} Nuclear stains have greater specificity since keratinocytes, melanophages, dendritic processes, etc. do not stain with these antibodies, decreasing the risk for overinterpreting melanocyte densities at surgical margins.⁴⁹ Cellular structure has been reported to be less perturbed with nuclear stains,^{106,123} though cellular detail will still be inferior compared to paraffin-embedded permanent sections. A study comparing Melan-A to MiTF found that the melanocyte density in the surrounding tumor-free chronically sun-exposed skin was higher with the Melan-A than with the MiTF and that the latter stain gave a more “crisp” outline of melanocyte nuclei.¹²⁴ The downside of nuclear stains is that the gain in specificity is countered by a loss of sensitivity. (Fig. 31-13 compares dual MART-1 immunostaining to SOX10 on an LM.)

Figure 31-13. Mart-1 (A) and SOX10 (B) immunostaining at 40× on a radial section of LM. The *arrows* indicate the approximate distal terminus of the LM as it extends from the center of the radial section to the perimeter surgical margin.

Making the distinction between the surgical border of LM/LMM and the melanocytic hyperplasia common in chronically sun-exposed skin is very difficult; therefore, an accurate calculation of melanocyte density can be extremely helpful, especially when a negative control is included where a comparison of densities between the LM/LMM and surrounding skin can help clarify surgical margins.^{17,29,39,41} The advantage of a nuclear versus a cytoplasmic stain is demonstrated by increased melanocyte densities with MART-1/Melan-A stains compared to MiTF presumably due to promiscuous staining of melanosomes in keratinocytes, dendritic processes, and melanophages.⁴⁹ The nuclear stains allow for an easier and more accurate count of melanocyte densities compared to cytoplasmic stains. There are a number of reports on the comparative densities of melanocytes in LM/LMM compared to chronically sun-exposed skin. Compare the MART-1 immunostain at 400x to the SOX10 immunostain at the same magnification in [Figure 31-14](#); the nuclear stain provides more clarity when making a specific density evaluation.

Figure 31-14. A. Mart-1 at 40×. B. SOX10 at 40×. C. Mart-1 at 100×. D. SOX10 at 100×. E. Mart-1 at 200×. F. SOX10 at 200×. G. Mart-1 at 400×. H. SOX10 at 400×.

Although MiTF adds specificity in comparison to MART-1/Melan-A, it is by no means perfectly selective, and can also bind to epitopes in dermal dendritic cells (antigen-presenting cells), some fibroblasts, Schwann cells, smooth muscle cells, and mast cells,^{105,123,125–129} and can lead to the false reporting of a nidus of invasive melanoma. For these reasons, one can never be overconfident in relying on MiTF and density counts as the single criterion in margin assessment.

SOX10

SOX10 (Syr-related HMG-box gene 10) is a neural crest transcription factor confined to the nucleus and is upstream to MiTF in that it regulates the expression of MiTF.⁸⁷ The expression of SOX10 is limited to melanocytes, eccrine glands, and Schwann cells, and unlike MiTF, is less apt to stain-associated fibroblasts and histiocytes (but more likely to stain desmoplastic melanomas compared to MiTF).¹³⁰ On the other hand, another study concluded that MiTF is slightly more sensitive than is SOX10 in tagging melanocytic nuclei.¹²² To evaluate the relative staining features of MART-1, SOX10, and H&E, [Figures 31-13 to 31-16](#) give some examples for comparison.

Figure 31-15. H&E staining at 100× (A), 200× (B), and 400× (C) on a radial section of an LM.

Figure 31-16. Comparison of the negative control with Mart-1 (**left**) and SOX10 (**right**).

A potential pitfall of SOX10 is found in a recent report of excisions of desmoplastic melanoma where a high percentage of excision specimens had SOX10 staining in surrounding scar tissue determined *not* to be part of the desmoplastic melanoma. It was hypothesized that regenerating schwannian cells in the scar were staining rather than the melanocytes.¹³¹ The authors cite two prior reports where SOX10 either weakly stained scar tissue (vs. the avid staining in desmoplastic melanoma)¹³⁰ or did not stain scar tissue at all.¹³² The discrepancy between these studies may be due to the use of different clones of the SOX10 antibody, differences in laboratory technique, or varying stages of maturation of the scar tissue examined.¹³¹ However, with regards to scar tissue, SOX10 has been reported to be less likely to stain fibroblasts and histiocytes than S100 or MiTF,¹³⁰ while maintaining a higher specificity.

SUMMARY

Regardless of which surgical technique is paired with which processing technique, the accuracy of surgery is reliant on the quality of the personnel involved in removing, processing, and interpreting the histology. If the process is performed with skill and attention to detail, the specific technique and process are less important than is the ultimate success in attaining the final goal: confirming negative histologic margins before the reconstruction is performed.

RADIATION THERAPY

Unlike in the United States, there is a bias toward treatment of LM with RT in Europe, Australia, and New Zealand. The advantage of RT is improved cosmesis with no surgical scarring outside of the original biopsy site as well as reduced morbidity in terms of subjecting the patient to both the excision(s) and reconstruction. Superficial RT penetrates to a depth of the dermoepidermal junction and then falls off exponentially.¹³³ Because LM tracks down the follicular appendages, it has been recommended that the RT dose be adjusted to achieve a depth of 5 mm since hair follicle depth ranges from 0.5 to 4.5 mm.¹³³

RT is hyperfractionated in the treatment of skin malignancies; a lower dose is given per fraction (RT treatment session) with a higher number of fractions delivered in total. Hyperfractionation has the advantage of less toxicity and consequentially less fibrosis. Hypofractionation is the converse, where a higher dose is given in a fewer number of treatments which is more convenient for the patient but results in greater morbidity.¹³⁴ RT can also be delivered to the skin in the form of brachytherapy with the application of a mold plate where the RT is diffusely delivered to the skin in a topical manner.¹³⁵ The determination of field size has been reportedly augmented by the use of a Wood's lamp and *in vivo* confocal microscopy in assessing tumor margins prior to treatment,^{136,137} and then adding an additional centimeter to the treatment field.¹³³

Two criticisms of RT as monotherapy for LM are that (1) it is hyperfractionated and (2) the cosmetic benefits tend to decline over time. In most RT clinics, treatment for LM requires 4 to 6 weeks of daily therapy (Monday to Friday) to achieve the intent to treat dosages of 54 Gray at 2 Gy

per fraction.¹³³ In the United States, many patients balk at this approach due to the time commitment. Although the initial cosmetic results of RT are excellent, over time the treated sites may begin to develop atrophy, hypopigmentation, telangiectasia, and decreased skin elasticity, making RT a less attractive option for the relative young patient. These consequences can be partially but not completely overcome by hyperfractionation.¹³⁸

RT must be used with great caution around free margins, particularly the eyelids. Posttreatment fibrosis can lead to ectropion formation with ensuing xerophthalmos.¹³⁹ An increasing number of dermatologists are using electronic surface brachytherapy (ESB) as an intraoffice nonsurgical treatment for nonmelanoma skin cancer, and although not approved by the Food and Drug Administration, there may be a temptation to apply ESB to LM. A recent report cites a male in his 60s with a BCC of the infraorbital cheek treated with ESB at a dose of 42 Gy in 12 fractions with a Xofig device (Xofig Inc) using a 20-mm cone.¹⁴⁰ A local recurrence of the BCC was noted within 10 months with contracture of the conjunctiva in the socket of a previously enucleated eye combined with lower lid ectropion with subsequent displacement and loss of his ocular prosthesis. There are no published data on the safety and efficacy of ESB for LM, and very little data with regards to nonmelanoma skin cancer.¹⁴¹

Despite risks at certain anatomic sites, in expert hands RT can be a very effective treatment for LM. A meta-analysis of nine studies using RT as monotherapy for LM was performed by Fogarty et al.¹³³ In this study, 349 LM lesions were treated with RT with a local recurrence rate of 5% with a median follow-up time of 3 years. Since the median time to recurrence of LM is 5.9 years,⁶² a 5% local recurrence rate at 3 years would be likely to increase with a follow-up time approaching 6 or more years. RT is a reasonable alternative to surgery, particularly in cases of very large tumors and/or elderly patients where the morbidity of surgery outweighs the inconvenience of hyperfractionated RT.

TOPICAL IMIQUIMOD 5% CREAM

Monotherapy

Imiquimod cream exploits Toll-like receptors that stimulate an inflammatory response when triggered that can treat genital warts^{142,143} and was subsequently been approved by the FDA for actinic keratosis and superficial BCC of the trunk.^{144,145} Imiquimod is an enticing option for patients with LM, as it avoids the morbidity and complications associated with surgery and RT. It has not been approved by the FDA for LM, but has been extensively used off-label as either monotherapy^{146–167} or as neoadjuvant therapy before surgery to decrease the size of the surgical margin requirement^{168,169} or as adjuvant therapy when the surgical margins for LM were close or positive.¹⁷⁰

There is a wide range of biological responses in patients treated with topical imiquimod, with some patients developing signs of vigorous inflammation while others demonstrating no inflammation whatsoever. Although an exact correlation between the degree of the inflammatory response and the complete clearance of LM has not been established, there is a trend toward higher efficacy with increasing inflammation when using imiquimod as a neoadjuvant therapy followed by complete excision.¹⁶⁹ Pooled data from 45 studies of topical imiquimod demonstrate that complete responses fall short of RT and staged surgical excisions, with complete clinical responses of 78.3% (95% CI, 73.6% to 82.9%) and complete histologic responses of 76.2% (95% CI, 71.4% to 81.0%).¹⁷¹

Neoadjuvant imiquimod followed by staged excision

The largest prospective controlled study to date using imiquimod in the neoadjuvant setting randomized 91 patients to receive either topical imiquimod alone 5 days a week for 3 months versus imiquimod in combination with tazarotene 0.1% gel added twice a week to augment drug penetration and enhance the inflammatory response.¹⁶⁹ After undergoing staged excisions, no evidence for residual tumor was seen in 78% of patients receiving the imiquimod/tazarotene combination compared to 64% of patients receiving imiquimod alone. Although the data showed a trend toward higher complete responses with greater inflammation, the difference did not meet statistical significance. Of note, 72% of patients had no residual tumor and were clear with 2-mm margins, while 28% required a second

stage of surgery with an additional 3.5-mm margin (total of 5.5-mm margins) for an average required margin of slightly less than 3 mm. This compares very favorably to the average requirement of 7.1-mm margins for LM not pretreated with topical imiquimod.¹⁹ Figure 31-17 addresses the purported advantage of neoadjuvant topical imiquimod for a hypothetical LM with a 10-mm clinical margin where the first scenario (A) calculates the surgical defect size for the average 7.1-mm requirement compared to the average 3-mm margin required for patients treated with neoadjuvant topical imiquimod prior to surgery. Figure 31-18 projects the 7.1-mm surgical margin requirement to a 3-mm margin requirement for a 10-mm LM on the Mona Lisa.

Figure 31-17. A. A 10-mm-diameter LM treated with a 7.1-mm margin. B. A 10-mm-diameter LM treated with a 3-mm margin.

Figure 31-18. A. A 10-mm LM with a 7.1-mm margin defect scaled down on the Mona Lisa. B. A 10-mm LM with a 3-mm margin.

OTHER NONSURGICAL OPTIONS

There are other potential nonsurgical treatments for LM that have not been tested to date. One candidate is local injection of a viralytic agent.

Talimogene laherparepvec (T-VEC) is a genetically modified herpes virus where the gene segments associated with disease have been excised and a gene coding for granulocyte macrophage colony stimulating factor (GM-CSF) has been inserted. It has been approved by the Food and Drug Administration for the treatment of metastatic melanoma.¹⁷² The viralytic agent is injected into accessible melanoma tumors or nodal metastases. The viruses demonstrate a predilection for melanoma cells and, once internalized, replicate, destroy the cell, and release virions and GM-CSF which attracts inflammatory cells.¹⁷³ T-VEC-treated patients have shown abscopal responses (effects in metastatic foci away from the injection site), suggesting that a systemic immune response may be stimulated.¹⁷⁴ Theoretically, this approach may have a therapeutic effect on LM as a means to avoid surgery.

RISK–BENEFIT CALCULATION

Perhaps the greatest challenge in the treatment planning for LM is making a risk–benefit calculation as accurately as possible in helping the patient in

choosing a treatment plan. Surgical approaches are quite effective in terms of complete responses, but often result in large surgical defects with consequential complicated reconstructive surgery. RT provides a gentler approach with better cosmetic outcomes, but may have a somewhat higher local recurrence rate and morbidity. Because LM is, by definition, an in situ tumor, it has no associated mortality risk assuming the diagnosis has been made accurately. The actual risk of an LM to the patient then becomes the statistical risk of its eventual progression to an invasive melanoma with an associated risk of metastases, directly related to the depth of invasion.

One study suggested that the lifetime risk of eventual transformation of LM to LMM is 4.7% for those age 45 and 2.2% for those age 65,²⁰ while another estimates the risk as closer to 50%.²¹ It, therefore, appears that only a minority of cases of LM are destined to become invasive.

Debloom et al. reported that in local recurrences of excised melanoma in situ, 22.6% of the recurrences were invasive, with a mean Breslow depth of 0.94 mm.¹⁷⁵ Examining over 2000 cases of LM in the Huntsman Cancer Institute database, approximately 20% of recurrent LM cases were invasive, although all recurrences had a Breslow depth of less than 1.0 mm and were staged as T1a (stage IA) LMMs. The 5-year mortality rate for a T1a melanoma is approximately 5%.¹⁷⁶

Assuming 5.9% local recurrence rate, with 20% of these invasive, and with the majority being <1.0 mm in depth (T1a tumors), a 0.06% mortality risk (or 6 deaths out of every 10,000 patients) would be expected.

The low mortality risk of treated LM in elderly patients invites complexity when choosing a therapeutic intervention. For younger or healthy patients, a 20% risk of invasion is a significant concern. In such patients, a more aggressive approach with the goal of complete response is reasonable. RT should be used carefully in the relatively young, since there is a tendency for a decline in the cosmetic appearance in treated sites over time combined with the increased risk of carcinogenesis, though that number is likely measured in decades and not years. In older patients, concern regarding developing skin cancer in irradiated sites becomes less of an issue, as does the worry about the potential for declining cosmesis in an RT-treated site. In patients over 80 years of age, the average life expectancy is much lower and may be heavily influenced by other comorbidities (diabetes, chronic renal failure, congestive heart failure, etc.). In such cases, a less aggressive

approach or even observation may be a reasonable course of action. In principle, the physician should partner with the patient in defining the treatment goal: reducing the risk that the patient will eventually die from a metastatic melanoma balanced by making every effort to minimize disfigurement and morbidity.

CONCLUSION

The state-of-the-art practice in terms of both diagnosing and treating LM/LMM is far from ideal. The discovery of a molecular marker to distinguish between a malignant and benign melanocyte continues to elude research scientists. Along with the myriad genetic changes that occur in melanoma, it is not possible at the current stage to predict which patients with LM are destined to progress to invasion and potential metastatic disease, especially as the great majority will likely live out a natural life expectancy with LM untreated.

Case 1

A

B

C

D

E

F

G

H

An 88-year-old female was referred for an LM of the left cheek diagnosed with an incisional biopsy. Residual pigment was evident at the time of referral with a very ambiguous clinical margin. An excisional biopsy was performed and closed with a double purse string. Invasion was detected to a depth of 0.36 mm with no other adverse features (Stage IA: T1a). A staged excision was performed and negative margins were confirmed after two stages and the defect was closed with a complex primary repair with a unilateral M-plasty. One can see the area of suspicion for residual tumor at the 10 to 12 o' clock position that, in retrospect, should have been taken on the first stage.

Case 2

A

B

C

D

E

F

G

An 84-year-old male was referred for an LM of the left malar cheek diagnosed with an incisional biopsy. An excisional biopsy was performed and closed with a double purse string. No invasion was detected and the patient was treated with topical imiquimod 5% cream Monday through Friday for 2 months. A conservative staged excision with 2-mm margins was performed 2 months after cessation of topical therapy with no signs of residual tumor histologically. The defect was closed with a complex primary repair with M-plasties.

Case 3

A

B

C

D

E

F

G

H

I

A 68-year-old female was referred for an LM of the left cheek diagnosed with an incisional biopsy. Residual tumor was seen clinically at the time of consultation, so an excisional biopsy was performed and closed with a double purse string. No invasion was detected and the patient was treated with neoadjuvant topical imiquimod 5% cream Monday through Friday for 2 months. A conservative staged excision with 2-mm margins was performed 2 months after cessation of topical therapy with a small amount of tumor centrally but negative-perimeter margins >2 mm from the outer edge. The defect was repaired with a complex primary repair.

Case 4

A

B

C

D

E

F

An 83-year-old female was referred for an LM diagnosed with an incisional biopsy. In contrast to the previously presented cases with invasion, this case was clinically very suspicious for invasion and demonstrates the inadequacy of the incisional biopsy in this case. An excisional biopsy was performed and closed with a linear closure and purse strings at the inferior and superior poles. Invasion was detected to a depth of 0.65 mm with no other adverse histologic features (Stage IA, T1a). A staged excision was performed with a 1.0-cm margin to the fascia. Residual in situ tumor was seen on the medial inferior edge (7 to 9 o' clock) and a second stage was performed and negative margins were confirmed. The defect was repaired with a complex primary repair.

Case 5

A

B

C

D

E

F

A 74-year-old male was referred for an LM diagnosed with an incisional biopsy. An excisional biopsy was performed and closed with a double purse string. No invasion was detected and he was treated with neoadjuvant topical imiquimod 5% cream Monday through Friday for 2 months. A conservative staged excision with 2-mm margins was performed 2 months after cessation of topical therapy. No residual tumor was detected and the defect was repaired with a complex primary repair.

Case 6

A

B

C

D

E

A 67-year-old male was referred for an LM from the left lateral chin diagnosed with an incisional biopsy. The clinical photograph shows some residual light brown pigment. An excisional biopsy was performed and closed with a double purse string. Invasive melanoma was seen on

histologic review to a depth of 0.48 mm with no other adverse histologic features (Stage IA, T1a). A staged excision was performed with a 1.0-cm margin to the fascia. Negative margins were confirmed on the first stage and the defect was closed with a rhombic flap with a modified Z-plasty.

Case 7

A

B

C

D

E

F

A 71-year-old male was referred for an LM of the left forehead diagnosed with an incisional biopsy. On examination, there is some faint residual brown pigment remaining. An excisional biopsy was performed and closed with a double purse string. Invasion was detected to a depth of 0.27 mm without any other adverse histologic features (Stage IA, T1a). A staged excision was performed with a 1.0-cm margin to the fascia with no signs of residual melanoma. The defect was closed primarily.

Case 8

A

B

C

D

E

A 52-year-old male was referred for an LM of the left forehead diagnosed with an incisional biopsy. An excisional biopsy was performed and closed with a double purse string. No invasion was detected and the patient was treated with neoadjuvant topical imiquimod 5% cream Monday through Friday for 2 months. Two months after cessation of topical therapy, a conservative staged excision was performed with 2-mm margins with no evidence for residual tumor. The defect was repaired with bilateral advancement flaps.

Case 9: Recurrent LM

A

B

C

D

E

A 79-year-old woman was referred for LM of the right forearm diagnosed with an incisional biopsy. A staged excision was performed with abundant central in situ tumor seen but negative-perimeter margins >2 mm were confirmed on the first stage. The defect was repaired with a bilobed transposition flap. The melanocyte density count was 19 melanocytes/400 $\times$ in the LM and 17 melanocytes/400 $\times$ in the negative control.

Three years later, a local recurrence was documented by the referring dermatologist and the patient was again referred for treatment. A staged excision was performed at the site of the local recurrence beginning with an 8-mm margin. There was residual melanocytosis centrally but with a widely negative-perimeter margin. The melanocyte density count of the re-excised LM was 28 melanocytes/400 $\times$ compared to 22 melanocytes/400 $\times$ in the negative control. The defect was repaired with a rhombic transposition flap.

Case 10

An 86-year-old male was referred for LM of the right zygomatic temporal region. The lesion was treated with neoadjuvant topical imiquimod 5% cream Monday through Friday for 2 months. Three months after cessation of topical therapy, he presented for a conservative staged excision with 2-mm margins.

- A. A transparent template around the LM was created at the commencement of topical imiquimod therapy. The template is reversed, a marking pen is used to trace the undersurface of the template (F means “front of the template” and the arrow indicates the 12 o’ clock position).

- B. The template is transferred onto the skin of the patient centered over an India ink tattoo placed at the time of the initial referral.

C. An approximate 2-mm margin is transcribed 360 degrees around the tumor outline.

D. A thin fusiform negative control is sampled from the right preauricular cheek.

E. The negative control site is sutured with an intradermal 5-0 monocryl and a 5-0 fast-absorbing gut on the surface.

F. The LM is removed with a 15-C scalpel to the level of the adipose plane.

G. Undermining is performed 360 degrees around the LM surgical defect and hemostasis achieved with electrocautery.

H. A plication traction suture is placed deep to the dermis to reduce tension on the intradermal sutures. An intradermal suture is then placed to allow for skin stretching during the laboratory processing time for the frozen sections and immunostaining.

- I. The specimen is taken to the laboratory and defatted and thinned with scissors to facilitate the cutting of en face vertical sections.

J. The specimen is quadrisectioned with a dissecting blade.

K. The perimeter of each quadrant is inked with its own color and then radial pie wedges are cut in about 3-mm widths. The first pie wedge of each quadrant is marked with black ink at the tip, so it can be identified as the first pie wedge as the specimens are viewed under the microscope in clockwise fashion.

L. The pie wedges are laid down on the cutting chucks in clockwise order on their sides to allow for vertical en face sectioning in the cryostat.

M. The pie-wedge radial sections are cut with vertical en face sections and stained with H&E, Mart-1, and SOX10.

N. The specimens are viewed under the microscope and a comparison of melanocyte density is made between the LM specimen and the negative control. In this patient, the melanocytosis seen centrally in the first quadrant had a density of 12 melanocytes/400 $\times$ compared to 10 melanocytes/400 $\times$ in the negative control which is not a difference great enough to judge as “residual LM.”

O. Once negative histologic margins have been confirmed, the defect is closed primarily.

CHAPTER 32 Histopathology for Mohs Micrographic Surgery

Teo Soleymani
Sumaira Z. Aasi

SUMMARY

- The Mohs surgeon must become expert at interpreting tangential sections and distinguishing normal structures from tumor.
- This may be challenging in certain situations depending on slide quality, section quality, and tumor subtype.

Beginner Tips

- An experienced technician is vital in the preparation of high-quality slides for evaluation.
- Aggregates of BCC may be distinguished from adnexal structures by peripheral palisading and retraction artifact.
- Examining multiple step sections may be helpful.
- Look closely at lymphocytic aggregates, as they often surround tumor nests.

Expert Tips

- Histopathologic interpretation of certain tumor subtypes, such as infiltrative BCC, may be challenging.
- These tumors should be differentiated from syringomas, desmoplastic trichoepitheliomas, and microcystic adnexal carcinomas.

Don't Forget!

- The differential diagnosis for SCCIS (and occasionally SCC) includes actinic keratosis, extramammary Paget's disease, inflamed seborrheic keratosis, verruca, pseudoepitheliomatous hyperplasia, and normal tangential sectioning of the epidermis.
- With moderate-to-poorly differentiated SCCs, perineural invasion is of concern.

Pitfalls and Cautions

- SCC may appear as single-cell infiltrates, which can be difficult to distinguish on frozen sections without the aid of immunohistochemical stains.
- There may be areas of focal necrosis, and often there is a prominent inflammatory lymphocytic (or lymphohistiocytic) infiltrate surrounding the malignant cells.

Patient Education Points

- Mohs surgery is unique in that one physician acts as both surgeon and pathologist.
- Educating patients regarding the complexity of the process, and the logistics behind tissue processing, may ameliorate stress regarding wait times between stages.

Billing Pearls

- If a lesion is biopsied for the first time on the day of Mohs surgery and a frozen section interpretation is made on the tissue, CPT code 88331 should be utilized with modifier 59.
- Billing for immunohistochemical stains is in addition to standard Mohs layer billing, and is generally billed on a per-specimen basis with code 88342 for the first antibody followed by 88341 for each additional antibody. If multiple separately identifiable antibodies are applied to the slide, use one unit of 88344.

CHAPTER 32 Histopathology for Mohs Micrographic Surgery

INTRODUCTION

Intraoperative histopathology is the cornerstone of Mohs micrographic surgery. The fundamental challenge for the Mohs surgeon is the accurate histologic identification and differentiation of benign versus malignant processes, as the goal of Mohs surgery is both to eradicate the cancer while concomitantly maximally conserving surrounding healthy tissue.

Often, features such as dense inflammation, chronic actinic damage with background solar elastosis, scar tissue, transected follicles, and other normal or benign cutaneous structures make differentiating benign versus malignant structures very challenging.

NORMAL ANATOMY

The skin consists of three distinct layers: the epidermis, the dermis, which is further divided into the superficial papillary and deeper reticular layers, and the subcutaneous fat.

The epidermis generally consists of four layers, with the exception of acral skin, which has an additional layer. The layer closest to the dermis is known as the basal layer or the *stratum basalis*, which consists of a single layer of slightly basophilic cuboidal cells with a relatively high nuclear-to-

cytoplasmic ratio. This basal layer is separated from the dermis by the *basement membrane zone*, a critical and highly specialized interface that allows for communication and anchoring of different cell types within the skin. Above the basal layer lies the spinous layer or *stratum spinosum*, which consists of cells with prominent intercellular connections, giving them a “spiny” shape. Above that lies the granular cell layer or the *stratum granulosum*, which consists of flat cells filled with stippled, coarse basophilic granules. The final layer consists of the cornified or keratinous layer, known as the *stratum corneum*. This layer is the most superficial and consists of anuclear cells typically arranged in a “basket-weave” pattern. In addition to the four layers mentioned above, there exists an additional fifth layer in acral skin, known as the *stratum lucidum*. This layer lies just underneath the stratum corneum and consists of pale, amorphous cells.

The dermis is comprised of a superficial section, known as the *papillary dermis*, and a deeper section, known as the *reticular dermis*. The papillary dermis contains a network of collagen and elastic fibers attached to and just underneath the basement membrane zone. The reticular dermis contains more dense bundles of collagen, small- to medium-sized blood vessels, and nerves, and extends to the subcutaneous fat. The subcutis, or subcutaneous fat layer, is composed of lobules of adipocytes separated by fibrous septae. Within the subcutis exist more abundant perforating blood vessels, nerves, and lymphatics.

Skin thickness varies depending on the region of the body. In addition, the skin contains numerous adnexal structures, such as hair follicles, sebaceous glands, eccrine and apocrine glands, as well as neurovascular bundles that vary in number and appearance based on anatomic location ([Fig. 32-1](#)). These adnexal structures can provide important clues as to the anatomic location of the body: for example, the presence of numerous small vellus hair follicles rooted superficially in the dermis may suggest facial skin, or the presence of apocrine glands, is suggestive of axillary or genital skin. In addition, certain dermal and subcutaneous features, such as the presence of striated skeletal muscle, or the presence of chronic actinic damage in the form of solar elastosis (seen as fragmented amorphous clumps of basophilic elastic fibers), can also provide clues as to the anatomic location and site.

Figure 32-1. Mohs section of normal skin demonstrating hair follicles cut on cross section and longitudinally.

COMMON TUMORS TREATED WITH MOHS MICROGRAPHIC SURGERY

Basal cell carcinoma

Basal cell carcinoma (BCC) is the most common malignant cutaneous neoplasm encountered with Mohs micrographic surgery. This cancer is composed of aggregates of basophilic cells that form a variety of shapes depending on the histologic subtype. In general, tumor cells have large, elongated, oval-shaped nuclei, and are characteristically basophilic, with little cytoplasm. Notably, there is a lack of marked atypia or mitoses. Within the aggregates, the basophilic cells display characteristic peripheral palisading of the nuclei (essentially a lining up of the nuclei parallel to each other).

Between and surrounding the basophilic tumor aggregates, there exists a distinctive fibromyxoid or mucinous stroma. Retraction artifact, another key

feature of BCCs, is the formation of clefts or clear spaces created from tissue processing. These clefts separate tumor aggregates from the surrounding stroma. Peripheral palisading and retraction artifact are two common histologic characteristics of BCC that are helpful in identifying tumor aggregates. This also helps differentiate BCC from similar-appearing adnexal structures or tumors. Necrosis may be seen in the center of large tumor aggregates, and individual necrotic tumor cells are sometimes seen. Neoplastic aggregates often have a surrounding lymphocytic inflammatory infiltrate, and there is usually a background of solar elastosis within the surrounding dermis.

In addition to the aforementioned histologic features seen in the vast majority of BCCs, there are additional characteristic findings unique to each histologic subtype of BCC as discussed below.

In *superficial BCCs*, small buds of basaloid cells extend downward from the underside of the epidermis and hair follicle epithelium into the superficial dermis (Fig. 32-2). In *nodular BCCs*, basaloid aggregates of various size and shapes are present in the dermis (Figs. 32-3 and 32-4). In *micronodular BCC*, the basaloid tumor aggregates are smaller and often diminish in size as they progress deeper in the dermis (Fig. 32-5).

Infiltrative BCC is often deeply infiltrative and poorly circumscribed (Fig. 32-6). Spiky, angulated basaloid tumor aggregates are interspersed haphazardly between the normal structures in the dermis, often without clear demarcation between tumor and surrounding stroma. The fibromyxoid stroma is usually not present (and may even appear overly fibrotic) and there is lack of the characteristic peripheral palisading in the tumor aggregates. Where it is common to find an epidermal connection with nodular and micronodular BCC in at least some histologic sections of the specimen, epidermal connections are often absent with infiltrative BCC. Variably, a dense lymphocytic infiltrate may be seen, and perineural invasion may be present as well.

Figure 32-2. Superficial BCC. The neoplastic aggregates are “budding” off the basal layer of the epidermis (*black arrows*) and have a slightly more blue/basaloid color than the adjacent epidermis. Note the retraction artifact and the mucinous stroma.

Figure 32-3. Nodular BCC and keratinizing BCC. At low-power magnification, note the variably sized nodular neoplastic aggregates composed of basaloid cells with palisading nuclei (*black arrows*). There are inflammatory lymphocytic infiltrates adjacent to and surrounding the neoplasm.

Figure 32-4. Nodular and keratinizing BCC. At higher-power magnification, note the keratinization occurring within the neoplastic aggregates (*black arrows*). This subtype of BCC is alternatively referred to as basosquamous carcinoma.

Figure 32-5. Micronodular BCC.

Figure 32-6. Infiltrative BCC demonstrating angulated cords and strand of basaloid cells. In this BCC, peripheral palisading is still appreciated as is mucinous stroma surrounding the neoplastic aggregates.

Importantly, in the majority of BCCs, more than one histologic subtype may be seen within a clinically solitary tumor (Fig. 32-7).

Figure 32-7. Mixed subtype BCC with superficial (*thick black arrow*), nodular, keratinizing (*medium black arrow*), and infiltrative (*thin black arrow*) features.

With superficial, nodular, and micronodular BCCs, the challenge for the Mohs surgeon is often to distinguish normal adnexal structures, particularly hair follicles that are transected at various levels and angles from neoplastic aggregates (Figs. 32-8 and 32-9).

Figure 32-8. The differential diagnosis of a BCC includes tangential sectioning of a normal or aberrant hair follicle, as seen here (*black arrow*). Since BCCs are thought to be derived from germinal matrix cells of primordial hair follicles, histologic features such as palisading basaloid cells are present in both neoplastic aggregates and normal hair follicles. The lack of retraction artifact, cytologic atypia, nuclear pleomorphism, and absence of mitoses helps to differentiate the two.

Figure 32-9. Another example of a tangentially sectioned and possibly aberrant hair follicle that can be mistaken for a nodular BCC (*black arrow*).

With infiltrative BCCs, this challenge also exists, along with the additional possibility that the spiky angulated “paisley-tie”- or “tadpole”-shaped basaloid aggregates are also seen in syringomas, desmoplastic trichoepitheliomas, and microcystic adnexal carcinomas (MACs).

Histologically, syringomas are composed of small, oval, “tadpole”-shaped aggregates that are often well demarcated, limited to the upper dermis, and have duct-like structures with monomorphous eosinophilic secretions in their lumina. Additionally, there is no clefting or retraction artifact seen with the aggregates in syringomas.

Desmoplastic trichoepithelioma is a tumor of follicular origin. Histologically, the tumor is small, well-circumscribed, often symmetric, plate-like, and confined to the papillary or superficial reticular dermis. Characteristically, the basaloid aggregates show evidence of follicular differentiation, and cystic structures with calcification may be present. A dense collagenous stroma surrounds the tumor aggregates without clefting or retraction space between them and the surrounding stroma. Perineural invasion and mitotic figures are absent.

Microcystic adnexal carcinoma (MAC) is histologically composed of angulated aggregates, cords, and strands of basaloid neoplastic cells. It is usually poorly circumscribed, asymmetric, and deeply infiltrative, often involving the subcutaneous fat and underlying skeletal muscle. Additionally perineural invasion is frequent and prominent. MACs demonstrate eccrine differentiation, and the presence of ductal structures help to differentiate them from infiltrative BCCs.

Pigmented BCCs are similar to nodular BCCs with foci of prominent melanin deposition. There may also be focal pigment incontinence, with melanophages seen in the dermis. Notably, there is no proliferation or nesting of melanocytes in the superficial dermis.

In *keratinizing BCCs*, the tumor aggregates display irregular shapes with areas of squamatization and keratin pearl formation. The squamatized cells may be enlarged and eosinophilic.

Other, less common subtypes of BCC include infundibulocystic and fibroepithelioma of Pinkus, and adenoid type. *Infundibulocystic BCCs* demonstrate differentiation toward the follicular infundibulum. They are often well circumscribed, with eosinophilic strands of squamous epithelium interspersed with basaloid buds in branching and anastomosing aggregates. Horn cysts are often present. Infundibulocystic BCCs may closely resemble basaloid follicular hamartomas histopathologically.

In *fibroepithelioma of Pinkus*, thin anastomosing strands of basaloid cells are seen attached to the epidermis and embedded in a background of ample fibromyxoid or mucinous stroma. Duct formation is often visible within the strands.

In *adenoid BCCs*, basaloid aggregates of neoplastic cells form small islands or strands in a lace-like pattern. There are clear, eccrine gland-like spaces in the middle of the islands (hence the “adenoid” pattern). Clefting or retraction artifact is often present, as is a fibromyxoid stroma.

Squamous cell carcinoma in situ

By definition, squamous cell carcinoma in situ (SCCIS) is limited to the epidermis, and invasion through the basement membrane is not seen (Figs. 32-10 through 32-13). Keratinocyte atypia involves the full thickness of the epidermis, which distinguished SCCIS from actinic keratosis, where the

atypia is confined to the lower levels of the epidermis. There is keratinocyte crowding in the basal layer, with disorganized, pleomorphic cells often arranged in a haphazard or “wind-blown” appearance. These crowded keratinocytes at the basal layer appear darker and more basophilic than surrounding healthy cells, with a high nuclear-to-cytoplasmic ratio, giving the lesion the “eyeliner sign.” The large pleomorphic neoplastic cells have hyperchromatic irregularly shaped nuclei and abundant eosinophilic glassy cytoplasm. Keratinocytes often appear vacuolated, and multinucleated cells may be present. There may also be individual necrotic keratinocytes. Mitotic figures are often seen, some of which are atypical. This is another distinguishing feature from actinic keratoses, which rarely display mitotic figures. The degree of cellular atypia may range from mild to severe. In addition, there is a lack of normal maturation of keratinocytes with ascent in the epidermis, as well as a lack of normal keratinization; the stratum corneum often demonstrates parakeratosis, as opposed to a normal basket-weave acellular keratin layer. In addition, due to this loss of maturation, the granular layer is often diminished or absent. Within the superficial papillary dermis, there is often a lichenoid or band-like lymphocytic infiltrate hugging the tumor along the dermal–epidermal junction.

Figure 32-10. SCCIS. Full-thickness atypia of keratinocytes is present in the epidermis, giving the cells a “wind-blown” appearance. The atypia is limited to the epidermis and there is no invasion into the dermis. Hyperchromatic and pleomorphic nuclei are appreciated even at low power.

Figure 32-11. SCCIS. Large pleomorphic, hyperchromatic nuclei are present throughout the epidermis. Focal areas of pink keratinization are also present along with parakeratosis. Note the diminished granular layer. A lymphocytic inflammatory infiltrate in the superficial papillary dermis hugs the neoplastic process.

Figure 32-12. SCCIS, eyelid. Full-thickness atypia of keratinocytes limited to the epidermis, especially where the epidermis appears acanthotic. Skeletal muscle fibers below the reticular dermis are present (*black arrows*).

Figure 32-13. SCCIS, eyelid. Higher-power magnification demonstrating the pleomorphic and hyperchromatic nuclei and atypical keratinocytes.

The differential diagnosis for SCCIS (and occasionally SCC) includes actinic keratosis, extramammary Paget's disease, inflamed seborrheic keratosis, verruca, pseudoepitheliomatous hyperplasia, and normal tangential sectioning of the epidermis.

In *actinic keratosis*, there is a lack of full-thickness atypia of the epidermis, which is essential in differentiating this entity from SCCIS. The atypia is restricted to the lower portions of the epidermis. There are rarely mitotic figures, and keratinocyte atypia does not involve follicular structures.

With *inflamed seborrheic keratoses*, there are often horn cysts and pseudohorn cysts in the epidermis, with overlying parakeratosis and mild reactive atypia. There is often an inflammatory lymphocytic infiltrate in the superficial papillary dermis. Importantly, there is no invasion into the dermis, and the atypia, if any, does not involve the full thickness of the epidermis; mitoses are rare.

With *verruca*, the epidermis is acanthotic, and there is hypergranulosis. Koilocytes are often present in the upper epidermal layers. In addition, dilated capillaries may be seen in the dermal papillae. There is no true atypia of keratinocytes. In *verrucous carcinoma*, however, a low-grade HPV-driven carcinoma, the histologic findings more closely resemble those of SCC.

Extramammary Paget's disease is an intraepidermal adenocarcinoma thought to be of apocrine origin. The epithelioid neoplastic cells are large, vacuolated, and are scattered throughout the epidermis in a pagetoid or "buckshot" pattern type that fans outwards with ascent through the epidermis. The neoplastic cells have a low nuclear-to-cytoplasmic ratio with vesiculated nuclei, basophilic nucleoli, and abundant pale cytoplasm. Cells may also be present along the dermal–epidermal junction but can infrequently invade the dermis.

Pseudoepitheliomatous hyperplasia is often a reactive result of various processes; a healing biopsy wound is the most common scenario a Mohs surgeon would encounter. The proliferation of the epithelium may resemble SCC, though the aggregates are often composed of large, uniform keratinocytes with abundant eosinophilic cytoplasm. Atypia, if any, is often mild and reactive, and mitoses are rare. Importantly, the keratinocytes are

well differentiated, and no nuclear atypia, hyperchromasia, or pleomorphism is present. Horn cysts and keratin pearls may be present. The epidermis and regenerating epithelial aggregates are often angulated, jagged, uneven, or even sharply pointed. Deeper sectioning into the tissue block may be helpful in distinguishing this reactive phenomenon from SCC.

Occasionally, tangential sectioning of a normal epidermis when trying to cut en-face Mohs sections can be misleading for novice Mohs surgeons. The absence of true atypia, and the lack of hyperchromasia, pleomorphism, or mitotic figures, helps distinguish this processing artifact from SCC or SCCIS. In addition, the presence of dermal papillae projecting through an epidermis that contains normal maturing keratinocytes is another useful clue confirming tangential sectioning artifact (Figs. 32-14 and 32-15).

Figure 32-14. Tangential sectioning of normal epidermis. At lower power, this normal epidermis that was tangentially sectioned during processing can easily be mistaken for an SCCIS at quick glance.

Figure 32-15. Tangential sectioning of normal epidermis. Closer examination reveals the evident lack of cytologic atypia, nuclear pleomorphism, and mitoses. Normal keratinocyte maturation helps to differentiate this artifact from malignant process.

Squamous cell carcinoma

Squamous cell carcinoma (SCC) is the second most common malignant cutaneous neoplasm encountered in Mohs micrographic surgery. In SCCs, the irregular aggregates of atypical neoplastic keratinocytes arising from the epidermis invade into the dermis ([Figs. 32-16 to 32-19](#)).

Figure 32-16. Well-differentiated SCC. Note the neoplastic aggregates (*thin black arrows*) surrounded by a dense lymphocytic infiltrate.

Figure 32-17. Well-differentiated SCC. At higher magnification, the moderate differentiation of this neoplasm is demonstrated by the presence of keratinization or “keratin pearl” formation (*thin black arrows*) adjacent to the tumor aggregates (*thick black arrows*).

Figure 32-18. Moderately differentiated SCC. At low-power magnification, variably sized eosinophilic neoplastic tumor aggregates are present in the dermis (*black arrows*).

Figure 32-19. Moderately differentiated SCC. At higher-power magnification, note the moderate differentiation of the neoplastic aggregates (*thick black arrows*), with keratinization or “keratin pearl” formation (*thin black arrows*).

The aggregates of neoplastic cells are often poorly circumscribed and vary markedly in size and shape. Neoplastic keratinocytes have vesicular nuclei, darker prominent nucleoli, and abundant eosinophilic cytoplasm. Nuclear pleomorphism is common, with atypical hyperchromatic nuclei and large nucleoli. Dyskeratotic cells show pyknotic nuclei and homogenous, bright, glassy eosinophilic cytoplasm. There are an increased number of mitotic figures within the neoplastic aggregates, often many of which are atypical.

Depending on the degree of differentiation of the neoplasm, the neoplastic aggregates may contain cells that closely resemble keratinocytes and demonstrate signs of keratinization such as the presence of keratin pearls (concentric whorls of eosinophilic parakeratotic cells). In contrast, poorly differentiated tumors contain cells that are less epitheloid and less eosinophilic and lack keratin pearls (Figs. 32-20 to 32-23).

Figure 32-20. Poorly differentiated SCC. Note the subtle tumor aggregates within the dermis, many of which are one- to two-cell layers thick (*thick black arrows*). These can be easily overlooked, particularly in the setting of an inflammatory lymphocytic infiltrate (*thin black arrows*) that often accompanies SCCs.

Figure 32-21. Poorly differentiated SCC. Higher-power magnification demonstrates the pleomorphic nuclei within the single-cell neoplastic strands and cords (*black arrows*).

Figure 32-22. Poorly differentiated SCC. At low power, the irregular, angulated neoplastic aggregates (*arrows*) may resemble an infiltrative BCC. Note the background solar elastosis and inflammatory lymphocytic infiltrate intermixed within the tumor.

Figure 32-23. Poorly differentiated SCC. At higher power, the cells (*thin black arrows*) are poorly differentiated with hyperchromatic pleomorphic nuclei, and in contrast to infiltrative BCCs, there is no retraction artifact, palisading, or surrounding fibromyxoid stroma. Note the difference between normal eccrine glands (*thick black arrows*) and neoplastic tumor aggregates.

The aggregates may be composed of a few cells and can even appear as single-cell infiltrates, making them very challenging for the Mohs surgeon to distinguish on frozen sections without the aid of immunohistochemical stains. There may be areas of focal necrosis, and often there is a prominent

inflammatory lymphocytic (or lymphohistiocytic) infiltrate surrounding the malignant cells.

With moderate-to-poorly differentiated SCCs, perineural invasion is of concern. Malignant keratinocytes may surround and encircle nerves or invade the perineurium or endoneurium (Figs. 32-24 and 32-25), and perineural invasion should be suspected in any tumor that demonstrates inflammation around nerves. Additionally, lymphovascular invasion, although rare, is a poor prognostic factor, and challenging to recognize on histologic sections.

Figure 32-24. Perineural SCC. Poorly differentiated SCC (*thick black arrows*) demonstrating perineural invasion (*thin black arrows*).

Figure 32-25. Perineural SCC at higher magnification.

In addition to these general histologic features seen in SCCs, several histologic subtypes demonstrate additional characteristic findings.

In *infiltrative SCCs*, the malignant cells are arranged in elongated strands, cords, or single cells that infiltrate deeply and haphazardly between collagen fibers within the papillary and reticular dermis (Fig. 32-26). There is a lack of keratinization, and connection with the epidermis is often subtle. There is often a scattered inflammatory lymphocytic infiltrate around the individual aggregates of neoplastic cells.

Figure 32-26. Another example of a poorly differentiated SCC, without perineural invasion, as demonstrated by uninvolved clean nerves cut longitudinally and on cross section (*thin black arrows*).

In *spindle-cell SCC*, the neoplastic epithelial cells take on a characteristic spindle shape; these cells form sheets or fascicles in a storiform or herringbone pattern invading into the dermis. Neoplastic cells have elongated, spindle-shaped nuclei, and bizarre, pleomorphic giant cells may also be present. Tumors often infiltrate deeply into the dermis; however, connection to the epidermis may still be present, which provides an important clue to the diagnosis and helps to differentiate spindle-cell SCC from other spindle-cell neoplasms.

In *acantholytic SCC*, there is acantholysis of the malignant neoplastic cells, creating pseudoglandular islands. The neoplastic epithelial cells often align around a space resembling a lumen that contains acantholytic atypical keratinocytes. Of note, the acantholytic cells and tumor islands may only be seen in a portion of the tumor. There may be focal keratinization, and acantholytic actinic keratosis may be seen directly adjacent to the tumor

Melanoma

The routine use of Mohs micrographic surgery for invasive malignant melanoma remains controversial, and is often reserved for unique situations such as acral and facial melanomas where tissue preservation is essential for functional outcome. However, in the setting of in situ disease, Mohs micrographic surgery for tumor extirpation has become increasingly accepted and utilized, with the aid of improved melanocytic immunohistochemical stains. Frozen sections must be cut thinner (in the order of 2 to 4 microns) in order to proficiently interpret melanoma in situ.

On routine hematoxylin and eosin staining, melanoma in situ demonstrates nested and confluent atypical melanocytes gathered along the dermal-epidermal junction. The lesions are often broad, especially in the case of lentigo maligna, in a background of solar elastosis. There may be pagetoid or “buckshot”-type spread of atypical melanocytes into the epidermis. The rete ridges are commonly effaced, and nonnested melanocytes often outnumber nested melanocytes. The nests, if there are any, vary in size and shape, and are often bizarre, elongated, or confluent. There is distinct asymmetry, and lateral borders are poorly defined. There may be a dense, lichenoid lymphocytic inflammatory infiltrate along the dermal edge of the lesion. Mitoses may be present, and there is often cytologic atypia.

In invasive malignant melanomas, poorly nested aggregates of atypical melanocytes extend beyond the dermal–epidermal junction into the dermis. The tumor is variably circumscribed with lateral asymmetry, and atypical melanocytes display a lack of normal maturation or dispersion with descent into the dermis. There is often prominent pagetoid or “buckshot” scatter into the epidermis. The rete ridges are commonly effaced, and non-nested melanocytes often outnumber nested melanocytes. Deep pigment may be present in melanocytic nests. The nests, if there are any, vary in size and shape, and are often bizarre, elongated, or confluent. There is often a lymphocytic inflammatory infiltrate at the base of the lesion, and plasma cells may be present as well. Mitoses, including deep mitoses, may be seen, and there is often cytologic atypia.

Historically, the utility of Mohs micrographic surgery for atypical melanocytic proliferations, including melanoma in situ, was limited given the poor diagnostic recognition of atypical melanocytes on frozen section. However, with the advancement of immunohistochemical stains and development of adequate staining techniques for frozen section tissue, the

resolution and diagnostic accuracy for atypical melanocytic proliferations have advanced greatly.

Currently, the most commonly used immunohistochemical stain used for intraoperative assessment of melanoma margins during Mohs micrographic surgery is the MART1 (Melan-A) stain. Immunohistochemical staining for MART1 is helpful in detecting both benign and malignant melanocytic proliferations, and has become the immunohistochemical stain of choice for the detection of malignant melanoma in situ using Mohs micrographic surgery. However, it is important to note that the MART1 antibody stain is a highly sensitive cytoplasmic stain; there is often significant background staining of melanocytes in the setting of chronic sun-damaged skin, and thus using MART1 to differentiate between benign and malignant melanocytic proliferations for tumor margin assessment may prove challenging. Additionally, MART1 does not stain desmoplastic melanomas. For a full discussion of Mohs surgery for melanoma in situ, see [Chapter 31](#).

Microcystic adnexal carcinoma

MAC is a malignant adnexal neoplasm that demonstrates eccrine differentiation. Clinically, it appears as a firm nodule or slow-growing plaque, most commonly on the face, with a greater predilection for women than men. Neoplastic cells are basaloid and uniform in shape, with monomorphous nuclei, a high nuclear-to-cytoplasmic ratio, and scant cytoplasm. The basaloid neoplastic aggregates form irregular, spiky, and angulated cords and strands traversing between collagen bundles. Often, the tumor aggregates are larger superficially and diminish in size with descent into deeper layers. Notably, the basaloid cords and strands may be very thin, and are sometimes comprised of just one cell layer, making the interpretation of frozen Mohs sections challenging. A dense hyalinized stroma, comprised of thickened collagen bundles, surrounds the neoplastic basaloid aggregates. Ductal structures are often present, and there is a lack of clefts or retraction artifact between tumor aggregates and surrounding stroma.

These histologic features may be similar to those found in infiltrative or morpheaform BCC, though with MAC the tumor is usually larger, poorly circumscribed, asymmetric, and deeply infiltrative, often involving the subcutaneous fat and underlying skeletal muscle. Additionally, MAC is considered a neurotropic tumor, and perineural invasion is common. The lack

of clefting, though also variable in infiltrative BCC, may also help to differentiate it from MAC. There is effacement and destruction of adjacent adnexal structures, which occurs less commonly in keratinocytic tumors. The stroma surrounding tumor aggregates is often sclerotic rather than fibromyxoid, as is the case with BCCs.

Dermatofibrosarcoma protuberans

Dermatofibrosarcoma protuberans (DFSP) is a fibrohistiocytic mesenchymal soft tissue tumor of intermediate malignant potential that has a marked tendency to recur, though it rarely metastasizes. It is believed that the cell of origin is an undifferentiated mesenchymal cell in the dermis, with fibroblastic, muscular, and neurologic features. Histologically, DFSPs are poorly delineated, with an infiltrative growth pattern. The tumor is comprised of bland, monomorphous, spindle-shaped neoplastic cells with elongated nuclei arranged in fascicles in a storiform or herringbone pattern (Figs. 32-27 and 32-28). Mitotic figures are rare, as is necrosis within the tumor. The tumor often involves the full thickness of the dermis, extending into the subcutaneous fat, and occasionally underlying skeletal muscle. Extension and infiltration of the spindled neoplastic cells into the subcutaneous fat form a honeycomb or lace-like pattern involving the fat lobules, and septal fibrosis is frequently seen. A Grenz zone between the tumor and overlying epidermis is often present. Adnexal structures are often effaced within the area occupied by the tumor. Importantly, DFSPs are positive for CD34 and negative for factor 13A, differentiating them from cellular dermatofibromas.

Figure 32-27. Dermatofibrosarcoma protuberans. The tumor is poorly circumscribed, infiltrative, and there is effacement of normal adnexal structures. Infiltration of the neoplastic cells into the subcutaneous fat forms a honeycomb pattern involving the fat lobules, often with septal fibrosis.

Figure 32-28. Dermatofibrosarcoma protuberans. At higher-power magnification, the tumor is comprised of fascicles of bland, monomorphous spindle-shaped cells arranged in a storiform pattern. Mitotic figures are rare.

Atypical fibroxanthoma

Atypical fibroxanthoma (AFX), also referred to as undifferentiated pleomorphic sarcoma, a term encompassing both AFX and malignant fibrous histiocytoma, is another malignant fibrohistiocytic mesenchymal soft tissue tumor that can occasionally be mistaken for a spindle-cell SCC. The tumor is densely cellular and is comprised of sheets of large, pleomorphic, atypical-appearing spindle-shaped cells haphazardly arranged in a storiform pattern (Figs. 32-29 and 32-30).

Figure 32-29. Atypical fibroxanthoma. At low-power magnification, the tumor is nonencapsulated, densely cellular, and comprised of sheets of large, pleomorphic, atypical-appearing spindle-shaped cells arranged in a storiform or random pattern.

Figure 32-30. Atypical fibroxanthoma. Higher-power magnification demonstrates neoplastic cells that have hyperchromatic, irregular nuclei with varying amounts of bland eosinophilic cytoplasm. Bizarre multinucleated giant cells are often present (*thick black arrows*), as are mitotic figures (*thin black arrows*), including atypical mitoses.

The neoplastic cells have hyperchromatic, irregular nuclei with varying amounts of bland eosinophilic cytoplasm. Bizarre multinucleated giant cells are often present, as are mitotic figures, including atypical mitoses. The tumor is nonencapsulated, starting beneath the epidermis, extending into the reticular dermis and sometimes subcutaneous fat, and has indistinct, infiltrative borders. A Grenz zone is often present, and the overlying epidermis is often atrophied or ulcerated. Of note, solar elastosis is almost always seen in the dermis adjacent to the tumor. AFX stains positively for CD10 (helping to differentiate between that and DFSP), vimentin, and procollagen, and may be positive for CD34 as well.

Sebaceous carcinoma

Sebaceous carcinomas are malignant tumors of sebaceous glands. The neoplastic cells display a variable degree of sebocyte differentiation, and are often markedly pleomorphic, with hyperchromatic, irregular-appearing

nuclei (Figs. 32-31 and 32-32). The tumor aggregates are often comprised of a haphazard mixture of immature nonvacuolated and mature vacuolated neoplastic sebocytes. The aggregates vary in size and shape, and numerous abnormal mitoses are often seen in individual tumor cells. Both solitary and en masse necrosis of neoplastic sebocytes is present as well. The tumor is asymmetric, poorly circumscribed, and has infiltrative borders that may be located superficially or deep extending into the subcutaneous fat. In addition, tumor aggregates may be discontinuous and multicentric. Importantly, the diagnosis of a sebaceous carcinoma, whether solitary or multiple, should raise the concern for Muir–Torre syndrome, and appropriate workup should ensue for germline mutations in mismatch repair genes including MSH2, MLH1, and MSH6.

Figure 32-31. Sebaceous carcinoma. At low-power magnification, the tumor aggregates are multicentric, asymmetric, and poorly circumscribed, extending into the subcutaneous fat, showing areas of necrosis.

Figure 32-32. Sebaceous carcinoma. At higher-power magnification, the neoplastic tumor cells display a variable to poor degree of sebocyte differentiation and are often markedly pleomorphic, with hyperchromatic, irregular-appearing nuclei. The aggregates of malignant cells are comprised of a haphazard mixture of immature nonvacuolated and mature vacuolated neoplastic sebocytes.

CONCLUSIONS

A thorough appreciation of histopathology is a prerequisite for performing Mohs surgery. While Mohs surgeons typically see patients with pre-existing pathology records, given the potential for collision tumors, the small sampling associated with minute shave biopsy specimens, and the potential for wrong-site surgery, it is critical to always rethink and reassess even ostensibly known diagnoses. Utilizing high-quality pathology sections coupled with an experienced and nuanced eye, Mohs surgery has the ability to provide the highest cure rate for nonmelanoma skin cancer while preserving maximal healthy tissue.

CHAPTER 33 Laboratory Techniques for Mohs Micrographic Surgery

Jonathan Kantor

SUMMARY

- Laboratory techniques dictate the quality of slides available for interpretation during MMS, and are therefore a critical step in ensuring high-quality patient care.

- While the technologist is responsible for creating the slides that are read by the Mohs surgeon, given the high stakes, the ultimate responsibility for ensuring high-quality interpretable slides rest with the Mohs surgeon him- or herself.

Beginner Pearls

- Ideally, the MMS laboratory should have two cryostats so that in the event of failure, patients are not overly inconvenienced.
- Several options are available for embedding tissue, including the heat-sink method, the glass-slide method, and the cryomold technique.

Expert Tips

- Tissue freezing medium adheres better to dermis than to epidermis, so deep nicks or hatch marks help not only with orientation, but with tissue adherence to the slide as well.
- Thin sections may be challenging to process, as they have a tendency to crumble or fall out of the embedding medium or rapidly flash-freeze prior to unrolling. Several approaches, including scoring with a warm scalpel blade and using cyanoacrylate glue, may be helpful.

Don't Forget!

- Orienting relaxing incisions medial to the epidermal edge on a 20- to 45-degree angle may help allow the tissue to gently flatten out.
- Charged, or so-called plus slides, may be helpful in encouraging tissue to adhere well to the slide.

Pitfalls and Cautions

- Slides should be wiped carefully; technicians who have trained with permanent section preparation may not be familiar with the rapidity with which Mohs surgeons begin to read slides.
- Formation of an opaque film over the slide may result from the use of incompatible clearing agents and coverslipping media.
- Most staining issues can be addressed by using compatible chemicals and by sufficiently blotting the slides and rack between reagents in order to avoid dilution and neutralization.

Patient Education Points

- Explaining to patients that all MMS laboratories are federally regulated may help bolster their confidence in the quality of an office-based laboratory.
- The laboratory area should be centrally located for ease of access and clearly marked so that patients do not inadvertently attempt entry.

Billing Pearls

- When billing Medicare for MMS, the laboratory's CLIA number must be attached to all claims.

CHAPTER 33 Laboratory Techniques for Mohs Micrographic Surgery

INTRODUCTION

High-quality histologic sections are the foundation on which Mohs micrographic surgery (MMS) is built. Indeed, the goal of complete margin control cannot possibly be attained if the Mohs surgeon is unable to effectively assess complete margins by reviewing crisp, clear, and complete histologic sections.

While much attention has historically been paid to MMS slide interpretation—and particularly post-MMS reconstruction—an appreciation of laboratory techniques for MMS slide preparation is of vital importance. In general, the technologist is responsible for creating the slides that are read by the Mohs surgeon, but given the high stakes, the ultimate responsibility for ensuring high-quality interpretable slides rest with the Mohs surgeon him- or herself. Therefore, understanding the fundamental laboratory techniques, as well as having a grasp of some of the most common troubleshooting scenarios, is of great value.

ACCREDITATION

Laboratory accreditation in the United States requires a CLIA certificate of compliance. MMS laboratories are considered high-complexity laboratories; as such, the laboratory director (usually the Mohs surgeon) must be a physician and meet certain requirements for experience, expertise, and training. Dermatology residency training, with its emphasis on dermatopathology, is a requisite for becoming a laboratory director. Anatomic pathologists may similarly be laboratory directors for high-complexity testing.

State law regarding laboratory licensure varies considerably, though minimum federal CLIA requirements must always be met. The MMS technician must similarly have a minimum level of training if they are to gross tissue, including an Associate's in Science degree or equivalent coursework and training. MMS laboratories that rely on the Mohs surgeon to perform all grossing do not require a technician to meet these criteria, since their work falls under a laboratory assistant category, though an experienced Mohs-trained histotechnician or histotechnologist is always desirable. Still, considerable variation in training and background for laboratory personnel persists.^{1,2}

When billing Medicare for MMS, the laboratory's CLIA number must be attached to all claims. Therefore, Mohs surgeons should bill under their own laboratories when performing MMS.

Several other options are available for accreditation, including the College of American Pathologists (CAP), which has additional requirements (and costs) beyond CLIA. Given the increased costs associated with this additional accreditation, it is infrequently pursued for MMS-only laboratories. Outside of the United States, laboratory accreditation approaches vary widely.^{3,4}

EQUIPMENT

The MMS laboratory includes several key pieces of equipment, foremost among them the cryostat. Essentially a microtome set inside of a freezer, modern cryostats permit the technologist to freeze tissue and section it appropriately for mounting on the slide. A wide array of cryostats are available from several manufacturers; given the substantial cost of repair, investigating purchase or lease options as well as included maintenance or

warranty plans is highly advisable. Ideally, the MMS laboratory should have two cryostats so that in the event of failure, patients are not overly inconvenienced. If this is not possible, an arrangement with another nearby laboratory is of great value, and may be required in some areas for accreditation. Regular maintenance is required for such precision equipment, and most cryostats are serviced at least annually.

Many MMS-specific laboratories rely on hand staining, though automated linear strainers may be used as well. The increased efficiency of automated strainers should be weighed against their cost and potential for breakdown. Manual staining equipment should always be available as a backup.

Staining is generally performed inside a ventilation hood. Two broad categories of hoods are available, those that are vented to the outside and those that are not (ductless). Ductless hoods may be more convenient when adding an MMS laboratory into an existing space, though this should be weighed against the long-term increased cost associated with frequent filter maintenance, replacement, and disposal. Given the risk of exposure to toxic chemicals, including formaldehyde and volatile organic compounds, the use of a ventilation hood is highly advisable.⁵

The laboratory environment is important for optimizing slide quality. Maintaining a low humidity and temperature permits efficient cryostat operation and minimizes the need for frequent defrosting. This is a particular challenge in geographic locations prone to high humidity.⁶

Safety equipment in the laboratory includes an eye wash station, gloves, and gowns. Emergency spill protocols should be in place as well; cat litter is an inexpensive alternative to specialized chemical spill response kits.

PREPARING FOR MOUNTING AND EMBEDDING

Prior to mounting and embedding the specimen, several key steps may help ensure that high-quality slides will result. Most importantly, tissue orientation must always be preserved. Some Mohs surgeons prefer to mark, nick, and orient the specimen while in the room with the patient; this approach minimizes the risk of incorrectly oriented specimens, and for experienced Mohs surgeons takes only a few seconds for most cases.

Alternatively, the technician may be delegated the task of tissue division, nicking, relaxing, and marking. In such cases, particularly careful attention should be paid to maintaining orientation as the involvement of an additional person introduces the possibility of error. Various nick and marking protocols are available, and are subject to individual surgeon preference.^{7,8}

Traditional MMS sections are taken at a bevel to permit flattening and ensuing margin interpretation. Some authors have suggested that only a minimal bevel is needed.⁹ There are, however, other options available to the Mohs surgeon, and some have advocated removing tissue using perpendicular incisions and relying on full-thickness relaxing incisions to permit the tissue to lay flat.^{10,11} One advantage of this approach is that it may lead to smaller ultimate defects, though it should be used with caution when removing thicker sections that may resist flattening even with significant radial relaxing incisions. Another advantage is that this approach may be less likely to transect the deep margin of tumor. Certain anatomic locations, such as the eyelids, can have sections removed perpendicular to the skin without compromising the ability to evaluate the margins.

Dehydrating the specimen reduces ice crystal formation and ultimately leads to higher-quality sections. While some have raised concerns that compressing the specimen could artificially shift tumor location, the net result of tissue dehydration by blotting or gently squeezing in gauze is higher-quality sections, and the theoretical concern regarding tumor shift has not been demonstrated.¹⁰

Several options are available for specimen processing. Until several decades ago, MMS specimens were typically bisected, though more recently processing MMS stages as a single specimen has come into vogue.^{12–14} This approach has the advantage of both minimizing the risk of orientation error while also being faster and more efficient for the technician. Moreover, laboratory errors may stem in large part from specimen division, and therefore processing sections in their entirety confers an additional significant quality advantage.¹⁵

When necessary, MMS specimens may be bisected. Thicker sections may benefit from relaxing incisions. Multiple relaxing incisions are sometimes needed, though increasing the depth of the relaxing incision may be more helpful than adding an additional shallow score. Several approaches to relaxing incisions are possible; the goal is to permit adequate tissue

flattening while avoiding full-thickness cuts that may result in false-positive or false-negative results when evaluating the deep margin.⁷ Orienting relaxing incisions medial to the epidermal edge on a 20- to 45-degree angle may help allow the tissue to gently flatten out.¹⁶

Some Mohs surgeons and technicians prefer to squash and freeze the specimen in place, arguing that this obviates the risk of relaxing incisions extending too deeply. While true, tissue that is under significant tension is more likely to curl back in when cutting, and may be more likely to be pushed out of the freeze medium en bloc (chunking out). Conversely, some surgeons place multiple deep and dramatic nicks in the tissue to permit it to lay flat (the blooming onion approach).¹⁷ This too may result in issues with deep margin interpretation.

When processing the specimen, note that tissue freezing medium (TFM) adheres better to dermis than to epidermis. Therefore, utilizing deep nicks or hatch marks helps not only with orientation, but with tissue adherence to the slide as well. When cutting tissue, orient the specimen so that the edge with the deepest nick (often 12 o'clock) is the first to be cut by the blade.

Given the better adherence of freezing medium to dermis than epidermis, thin sections may be challenging to process, as they have a tendency to crumble or fall out of the embedding medium and, if the edges are curled, rapidly flash-freeze prior to unrolling. Several approaches, including scoring with a warm scalpel blade and using cyanoacrylate glue, have been proposed as workarounds in these situations.^{18,19}

Fat and cartilage require special considerations. Fat freezes at a lower temperature than skin, and therefore, if a fatty specimen is processed in a traditional fashion it often does not have sufficient time to freeze prior to sectioning.²⁰ Flash freezing in an isopentane histobath, or using a Miami Special device in a liquid nitrogen bath, may be helpful in such cases.²¹ Alternatively, use of liquid nitrogen sprayed, poured, or painted over the section may also help drop the temperature of the fatty section, though the latter approach may only freeze the fat inconsistently, leading to less than optimal sections. Delaying sectioning to permit the entire specimen to drop to a lower temperature is another option, though this is generally not favored. Finally, cutting thicker sections is another option when fat cutting remains a challenge, though this approach yields sections that may be more difficult to interpret.

Cartilage may shatter when cut at too low a temperature, and its native inelasticity, which makes it so valuable during surgical reconstruction, means that encouraging it to lay flat for an ideal section may be a challenge. Combining deep relaxing incisions centrally and peripherally with a slightly higher cutting temperature may yield the best results. Cartilage also has a tendency to wash off the slide during staining, and therefore a gentle touch is of great value.

Finally, wedge excisions may be particularly challenging to process, given the three-dimensional nature of the margins that need to be examined. Classically, the lateral margins are spread, separated, and processed in such cases, or the wedge is bisected and spread apart in a butterfly fashion. Processing wedges in each plane in a serial fashion has also been described.²²

EMBEDDING

Several options are available for embedding tissue. Commonly used approaches include the heat-sink method, the glass-slide method, and the cryomold technique. Myriad other specialized options are available including the Cryoembedder, Miami Special, Cryocup, and CryoHist, though a litany of other approaches have been advocated in the past as well.^{10,11,23–26}

Heat-sink method

The heat-sink method is one of the simplest methods of embedding. The inked, nicked, and relaxed specimen is placed on a handheld heat sink, and the epidermal edges are flattened in place using forceps (Fig. 33-1). This approach may also be used directly with the freeze bar in a cryostat, though using a handheld heat sink is ergonomically more straightforward. The flattening is time sensitive, as fresh tissue adheres well to the heat sink where it freezes immediately, but frozen tissue tends to rest in place with minimal adherence. If necessary, optimal cutting temperature (OCT)-compound rescue may be used to help adhere the edges in place. OCT is placed on a room-temperature chuck, which is then placed inside the cryostat and allowed to freeze (Fig. 33-2).

Figure 33-1. The heat-sink method is one of the simplest methods of embedding. The inked, nicked, and relaxed specimen is placed on a handheld heat sink, and the epidermal edges are flattened in place using forceps.

Figure 33-2. OCT is placed on a room-temperature chuck, which is then placed inside the cryostat and allowed to freeze.

OCT is also placed over the adhered specimen on the heat sink (Fig. 33-3), which is placed specimen-up on the cryostat freeze bar. Once the OCT begins to set (Fig. 33-4), the chuck and heat-sink OCT are gently pressed together and allowed to freeze in place (Fig. 33-5). Once fully set, the heat sink is twisted off the chuck (Fig. 33-6), additional OCT is added, and the specimen is ready for sectioning (Fig. 33-7). The advantage of starting with a room-temperature chuck is that it permits the OCT to enter the crevices and adhere more effectively.

Figure 33-3. OCT is also placed over the adhered specimen on the heat sink.

Figure 33-4. The OCT begins to opacify and set.

Figure 33-5. The chuck and heat-sink OCT are gently pressed together and allowed to freeze in place.

Figure 33-6. Once fully set, the heat sink is twisted off the chuck.

Figure 33-7. The specimen is then ready for sectioning. Note that the deep 12 o'clock nick is oriented downwards.

CHAPTER 35 Surgical Scar Revision

Mary L. Stevenson
John A. Carucci

SUMMARY

- Cutaneous scars are a critical consideration for the dermatologic surgeon, as patients often judge the ultimate success of their surgery based on the final appearance of the surgical scar.
- Numerous techniques are available for surgical scar revision, ranging from topical therapy to laser treatment to surgical intervention.

- Timing of scar revision is usually planned several months following surgical intervention to allow for the scar to improve naturally, though in some instances—such as cases of hypertrophic scarring and keloid formation—more rapid intervention may be appropriate.
- Minimally invasive approaches, such as topical and laser therapy, may be considered sooner.

Beginner Pearls

- The majority of favorable scars are produced within RSTLs.
- Scars continue to mature and remodel for up to 12 months, and the appearance of scars continues to improve even beyond one year.
- Intralesional corticosteroids are the mainstay of treatment for hypertrophic and keloidal scars.

Expert Tips

- The 585-nm pulsed dye laser (PDL) was the first laser to gain wide acceptance for use in treating scars postoperatively, though the 532-nm KTP laser or IPL may also be used for erythema in surgical scars.

- Fusiform excision, Z-plasty, V–Y advancement flaps, and subcision may all be used to improve scar cosmesis as well.

Don't Forget!

- Patients who are pregnant or immunosuppressed should not be injected with 5-FU.
- Fractional ablative and nonablative laser resurfacing has also been used for scar revision.
- Dermabrasion is often performed 4 to 8 weeks postoperatively when tissue remodeling is taking place, though it may also be used significantly later.

Pitfalls and Cautions

- Ultimately, tension is the greatest enemy of the surgeon, and excess tension is responsible for many scar-related complications.
- Therefore, meticulous surgical design coupled with outstanding suturing technique may mitigate many scarring complications.

Patient Education Points

- Explain to patients prior to any procedure that every surgical procedure results in a scar.
- Ideally, a preoperative explanation that every surgical procedure may ultimately benefit from a staged approach helps patients understand that additional treatment may be beneficial, and helps them anticipate this eventuality rather than see it as a complication.

Billing Pearls

- Z-plasty may be billed using the 140XX series codes and is often reimbursable from insurance.
- Most laser- and light-based treatments are excluded from insurance coverage.

CHAPTER 35 Surgical Scar Revision

INTRODUCTION

Cutaneous scars are a critical consideration for the dermatologic surgeon, as patients often judge the ultimate success of their surgery based on the final appearance of the surgical scar. Revision of surgical scars is sometimes necessary for functional reasons, aesthetic reasons, or both. Numerous techniques are available for surgical scar revision, ranging from topical therapy to laser treatment to surgical intervention. Consideration of the texture, contour, erythema, hypo- or hyperpigmentation, and quality of the scar will affect the revision technique employed. Knowledge of these techniques allows the surgeon to achieve the best results for their patient. An appreciation of relaxed skin tension lines (RSTLs) is essential to understanding scars and scar revisions, as the majority of favorable scars are produced within RSTLs. Scars continue to mature and remodel for up to 12 months, and the appearance of scars continues to improve even beyond 1 year.¹ Timing of scar revision is usually planned several months following surgical intervention to allow for the scar to improve naturally, though in some instances—such as cases of hypertrophic scarring and keloid formation—more rapid intervention may be appropriate. Minimally invasive approaches, such as topical and laser therapy, may be considered sooner.

In an effort to standardize treatment of scarring, the International Advisory Panel on Scar Management released a consensus statement on the management of scars in 2002 consolidating evidence-based medicine and expert opinion.² In 2014, updated recommendations were published and since then further technologies and data have been released.^{3,4} These

recommendations include topical therapies, intralesional agents, laser therapy, and radiation therapy for the treatment of scars. Surgical revision may also be employed.

INTRALESIONAL APPROACHES

Intralesional corticosteroids are the mainstay of treatment for hypertrophic and keloidal scars.^{2,5} Injection of triamcinolone acetonide has been an evidence-based approach since 1966 when the first controlled study of its use was reported.⁶ Used in concentrations ranging from 10 to 40 mg/mL, it can also be combined with intralesional 5-fluorouracil (5-FU), laser therapy, or surgical intervention with injection at the time of treatment to prevent keloidal scar formation (Table 35-1). Adverse effects of intralesional corticosteroid injection include atrophy, telangiectasia, and hypopigmentation.

Table 35-1. Intralesional Options

Triamcinolone
5-FU
Combination approaches

In 1999, Fitzpatrick reported on nine clinical years of experience of injection of 5-FU for the treatment of hypertrophic and keloidal scars.⁷ Patients were treated with 5-FU at a concentration of 50 mg/cc with doses ranging from 2 to 50 mg per treatment with injections occurring up to three times weekly, with reduction in frequency to every 4 to 6 weeks following the improvement of scars. He also combined 0.9 cc of 5-FU at 50 mg/cc and 0.1 cc of triamcinolone acetonide at 10 mg/cc and found these injections to be less painful. Re-excision of keloids with intraoperative intralesional 5-FU and/or triamcinolone is also highly effective (Fig. 35-1).⁸ Patients who are pregnant or immunosuppressed should not be injected with 5-FU.

Figure 35-1. Removal of keloid followed by injection of triamcinolone plus 5-fluorouracil: (A) preoperative view; (B) postoperative view. Patient underwent monthly injections of triamcinolone and 5-fluorouracil for 4 months.

LASER- AND LIGHT-BASED APPROACHES

The original 2002 scar management consensus guidelines addressed CO₂ lasers, argon lasers, and pulsed-dye laser (PDL) therapies. Since then, numerous other therapies have emerged including ablative and nonablative fractional lasers. [Table 35-2](#) is a summary of minimally invasive approaches to scar revision.

Table 35-2. Minimally Invasive Approaches to Scar Revision

CO ₂ laser
Pulsed-dye laser
IPL
Dermabrasion
Nonablative fractional resurfacing
Ablative fractional resurfacing
Microneedling

The 585-nm PDL was the first laser to gain wide acceptance for use in treating scars postoperatively.^{4,9} The PDL targets oxyhemoglobin as its chromophore, and is effective in targeting small blood vessels within scar tissue, improving erythema. This approach may also be used after superficial flap necrosis (Fig. 35-2). Additionally, PDLs have been used for hypertrophic scars and keloids, leading to possible improvement in scar pliability.⁹ While the exact mechanism of action has yet to be elucidated, it is postulated that microvascular destruction and tissue ischemia may lead to collagen remodeling, and that PDL treatment may reduce the higher levels of transforming growth factor-beta which is found in keloids.^{10,11} Sub-purpuric settings with longer pulse durations and lower fluences may demonstrate superior outcomes to purpuric settings in surgical scars, though both are effective.^{10,11} Adverse effects include erythema, swelling, ecchymoses, and hypopigmentation. Alternatively, the 532-nm potassium titanyl phosphate (KTP) laser or intense pulsed light (IPL) may also be used for erythema in surgical scars.

Figure 35-2. PDL for telangiectasia and erythema after flap necrosis. (A) Defect after cancer removal. (B) Rotation flap repair. (C) Distal necrosis at suture removal. (D) Result after conservative wound care and three treatments with PDL.

Introduced in 1953, dermabrasion is another useful modality for treating surgical scars.¹² Dermabrasion is often performed 4 to 8 weeks postoperatively when tissue remodeling is taking place, though it may also be used significantly later.^{13–15} The most common adverse effects include hypo- and hyperpigmentation, persistent erythema, infection, viral reactivation, and rarely keloid formation. Following dermabrasion, ablative resurfacing with high-energy, short-pulsed CO₂ lasers or low-power continuous-wave CO₂

lasers was popular as an effective means of skin resurfacing, though they have significant healing time and postoperative wound care.^{16–18} In comparison to dermabrasion, ablative CO₂ lasers offer the advantage of a bloodless field and increased precision with more selective tissue ablation.¹⁹ However, patients experience crusting, oozing, and often persistent erythema with re-epithelization at approximately 1 week and erythema persisting for 4 to 8 weeks. Adverse effects include hypo- and hyperpigmentation, milia formation, infection, viral reactivation, and scarring.

More recently, fractional ablative and nonablative laser resurfacing has been used with increasing frequency for scar revision. In fractional resurfacing, the laser creates microthermal zones (MTZs) of injury just below the skin surface, with selective necrosis and neocollagenesis.²⁰ This technology specifically spares the tissues surrounding each individual microscopic wound, which allows for faster healing and less downtime. The 1550-nm erbium-doped fiber laser, which utilizes nonablative fractional resurfacing, was shown to be effective in surgical scars.²¹ In a split-scar study comparing nonablative fractional resurfacing with PDL following Mohs micrographic surgery, nonablative fractional resurfacing showed improved outcomes for overall cosmesis, dyspigmentation, hypopigmentation, thickness, and texture of scar.²² The most common posttreatment events include dry and flaking skin, erythema, edema, acneiform eruption, and viral reactivation, with healing occurring within 1 week.^{23,24} Ablative fractional resurfacing has been used as well.^{25,26} Sparing surrounding areas of tissue, ablative fractional resurfacing allowed for re-epithelization and resolution of erythema within 7 days, with deeper zones of tissue ablation.^{26,27} Ablative fractional resurfacing may be more effective than nonablative fractional resurfacing, and has shown utility in thicker and atrophic scars.^{1,27,28} A small series of atrophic scars showed that three ablative fractional resurfacing treatments at 1- to 4-month intervals resulted in a 38% mean reduction in scar volume and 35.6% mean reduction in maximum scar depth.²⁷ In comparison to PDL, which is more effective at improving vascularity within scars, ablative fractional resurfacing demonstrates superior results in improving scar contour, including scar thickness and pliability.²⁹ In a postthyroidectomy surgical scar study comparing fractional ablative laser resurfacing to nonablative fractional

laser resurfacing, fractional ablative laser resurfacing tended to improve scar thickness, while nonablative fractional laser resurfacing was superior at improving scar color including erythema and pigmentation.^{30,31} This benefit should be weighed against the increased downtime seen with ablative approaches.

Finally, microneedling and microneedle fractional radiofrequency have also been used to improve the functional and aesthetic outcomes of surgical scars. Subcision, with the insertion of a needle through punctured skin for the correction of depressed scars, was first reported in 1995.³² A small randomized clinical trial comparing nonablative fractional laser and microneedling in atrophic acne scars showed both to be efficacious, with microneedling having fewer adverse effects including hyperpigmentation.³³ Microneedling has also been shown to increase the viability of skin flaps in animal models, though there are no reported studies of its efficacy in the treatment of surgical scars to date.³⁴ Currently on the horizon, radiofrequency microneedling has also been shown to improve acne scars by damaging the reticular dermis, resulting in tissue remodeling and the increased formation of elastin and collagen.^{35–37}

SURGICAL TREATMENT

Fusiform excision is the most basic technique for surgical scar revision. The entire length of the scar is excised with as narrow a margin as possible resulting in a longer—and ideally narrower—scar (Fig. 35-3).¹ Such revised fusiform excisions generally have a length-to-width ratio well in excess of 3:1, with 30-degree angles at the apices. In lieu of complete scar excision, partial removal can alternatively be performed, as in the case of the standing cone revision (Fig. 35-4). Table 35-3 is a summary of surgical approaches to scar revision.

Table 35-3. Surgical Approaches to Scar Revision

Figure 35-4. Scalpel revision of standing cone. (A) View at closure of defect from Mohs for incompletely excised BCC on the lip. (B) Standing cone on inner lower lip covered teeth with full smile. (C) Immediate postoperative view following excision of standing cone.

Z-plasty is another commonly employed technique that reorients the direction and tension vectors of a scar, allowing it to be aligned within RSTLs (Fig. 35-5).³⁸ It is indicated for webbed scars, contracted scars, and scars that are greater than 30 degrees from the RSTLs.³⁹ In this technique, the original scar forms the common diagonal, and two arms of equal length to the original scar are extended in either direction at a set angle.⁴⁰ The original scar is then excised, with incisions made along arms of the Z, with subsequent undermining and transposition of the two triangular flaps to create a new scar perpendicular to the original one. The size of this angle and the length of the original scar determine how much scar lengthening will occur

when the tension is redirected, with larger angles producing a greater lengthening in the scar as well as a greater reorientation of the direction of the scar. The traditional angle of 60 degrees lengthens the scar by 75%. Multiple Z-plasties may also be used in succession for longer scars. For a detailed discussion of Z-plasty techniques, see [Chapter 27](#).

Figure 35-5. In a Z-plasty, two arms of equal length to the original scar are extended in either direction at a given angle. The original scar is then excised with incisions made along these arms followed by transposition of these two triangular flaps to create a new scar that is perpendicular to the original one. This results in scar lengthening and is thus useful for correction of webbing and free margin distortion.

In comparison, the W-plasty technique does not result in the lengthening of the original scar and involves the creation of multiple, short, connected, triangular advancement flaps that run along the length of the original scar ([Fig. 35-6](#)). This technique is often employed for shorter scars located on the forehead or cheek with an M-plasty at the end of the incision to prevent scar extension.⁴¹ Additionally, in comparison to the Z-plasty which involves excision of the scar and incisions along the arms, the W-plasty involves the excision of the scar and a small amount of surrounding normal skin.³⁹ A more complex variation of the W-plasty is a geometric broken line closure in which a random pattern of geometric patterns is interposed in order to create a random irregular scar.^{39,41}

Figure 35-6. W-plasty technique involves the creation of multiple, short, connected, triangular advancement flaps that run along the length of the original scar. This does not result in lengthening of the scar as is the case with Z-plasty.

A V–Y advancement flap may be used at free margins such as the lip or eyelid in order to correct contraction which may result in elevation or depression of the tissue.⁴⁰ This technique may be used to correct ectropion on both the upper and lower eyelids.⁴² A V-shaped incision is made surrounding the contracted scar, with wide undermining performed circumferentially. This V-shaped pedicle is then *pushed* forward by side-to-

side closure of the tail of the Y posterior to the now-advanced pedicle, altering the tension on the contracted scar and allowing for an improved cosmetic outcome ([Fig. 35-7](#)).⁴⁰

B

Figure 35-7. Rotation flap with back cut and periosteal anchoring suture to correct medial lower lid ectropion. (A) Preoperative view with ectropion resulting in tearing. (B) Immediate postoperative view. (C) Patient achieves normal eye closure with resolution of tearing.

Subcision may be performed to achieve ideal contour in cases of trapdoor deformity. An incision is made at the distal edge of the elevated flap (Fig. 35-8). Undersurface debulking is performed followed by re-approximation of the flap. Concavity revision may be more challenging, though a free cartilage graft may be used to raise the nasal tip to improve the appearance of a failed full-thickness skin graft (Fig. 35-9).

(B) Free cartilage graft was obtained from the antihelix. (C) Graft was placed after incision and elevation of site. (D) Contour improvement at 2 months.

CONCLUSIONS

Scars are an inevitable consequence of cutaneous surgery. The goal of surgical scar revision is improved functionality and cosmesis. Consideration of the type of scar, location of the scar, quality and texture of the skin, RSTLs, and other considerations are all essential in planning an ideal revision. Notably, regard for tension on the healing wound is of paramount importance. Use of nonsurgical and surgical techniques often leads to the most ideal revision. Meticulous planning, including an appreciation of the timeline for various scar revision techniques, is also essential. By appreciating the ever-expanding armamentarium of surgical scar revision techniques, the surgeon may better care for their patients and produce optimal outcomes.

CHAPTER 36 Managing Surgical Complications

Eileen Axibal
Ramin Fathi
Mariah Ruth Brown

SUMMARY

- Dermatologists perform approximately 9.5 million procedures yearly in the United States alone.
- The rate of complications remains under 1%, and the rate of serious complications is vanishingly rare.
- The risk of bleeding is the greatest in the first 24 hours postoperatively and is most frequent in the first 6 hours.

- Prophylactic antibiotics are only indicated in specific circumstances (surgery on the mucosa or infected skin) to prevent joint infection, endocarditis, and surgical site infection.

Beginner Tips

- Be able to recognize signs and symptoms of vasovagal reaction, epinephrine reaction, anesthetic overdose, and anaphylaxis.
- To avoid a delayed suture reaction, or spitting suture, place absorbable sutures deep in the dermis, cut sutures at the knot, and close wounds with minimal tension.

Expert Tips

- Digital blocks with lidocaine with epinephrine are considered safe, though the surgeon should avoid using more than 2 to 4 mL of anesthesia per digit, as the mass effect of the anesthetic volume added can lead to nerve and artery compression.

Don't Forget!

- The nerves at the greatest risk for injury during cutaneous surgery are the temporal and marginal mandibular branches of the facial nerve and the spinal accessory nerve. Know the anatomical danger zones of these nerves, but also appreciate that nerve location cannot be precisely identified by anatomic location due to extensive individual variability.

Pitfalls and Cautions

- Poor closure design can lead to tension on an anatomic free margin and subsequent cosmetic and functional impairment. The surgeon should design closures that place tension perpendicular to the free margins.

Patient Education Points

- While complications in dermatologic surgery are uncommon, even a 1% complication rate translates into a risk of possibly weekly complications given the volume of procedures performed by many dermatologic surgeons.
- Taking time to actively consent patients and inform them of possible complications may lead to a significant improvement in patient satisfaction.

Billing Pearls

- Dermatologic surgeons should be familiar with global periods; most complications treated within the global period of a given procedure cannot, by definition, be billed for separately.
- Weigh the value of charging patients for revision procedures against the goodwill fostered by performing these procedures as a courtesy.

CHAPTER 36 Managing Surgical Complications

INTRODUCTION

Dermatologists perform approximately 10.5 million procedures each year.¹ Of these, about 68% are cosmetic procedures and the remainder are procedures such as Mohs micrographic surgery (MMS) and surgical excisions.¹ The vast bulk of dermatologic surgery is performed in an outpatient, office-based setting.

The safety and efficacy of dermatologic surgical procedures has been supported by multiple clinical studies. A prospective study following 2370 surgical procedures, including 934 MMS cases, over a 1-year period found a total of 56 surgical complications in 51 patients. Bacterial wound infections occurred in 13 cases (0.5%) and bleeding complications occurred in 5 cases (0.2%).² A prospective multicenter study examined the intraoperative and postoperative adverse events at 23 centers performing MMS. Among 20,821 MMS procedures, there were 149 adverse events (0.72%), including 4 serious events (0.02%), and no deaths were reported. Of the adverse events, 61.1% were infections, 20.1% were wound dehiscence or partial- or full-depth necrosis, and 15.4% were related to bleeding or hematomas.³ Even for staged interpolation flaps, among the most invasive of dermatologic surgery procedures, the complication rate remains quite low. A review of 653 staged interpolation flaps at a single center revealed no major complications. Minor complications consisted of active bleeding requiring physician intervention (8.4%), hematoma (0.4%), postoperative infection after initial surgery (1.7%), and after division of pedicle (3.4%), dehiscence (0.5%), and partial- (2.3%) or full-thickness (0.6%) flap necrosis.⁴ Noninvasive to

minimally invasive cosmetic dermatologic procedures are also associated with a low rate of adverse events. A multicenter, prospective cohort study of procedures performed using laser and energy devices, injectable neurotoxins, and soft-tissue augmentation materials (20,399 total procedures) reported only 48 adverse events (0.24%) and no serious adverse events.⁵

Overall, the risk of minor adverse events in dermatologic surgery is low, and severe complications such as hospitalization and death almost never occur. Nonetheless, complications still arise in dermatologic surgery and surgeons must be able to successfully prevent, diagnose, and manage these complications. This chapter will address preoperative techniques to minimize adverse events in dermatologic surgery, as well as the identification and management of complications in the intraoperative and postoperative time periods.

PREOPERATIVE CONSIDERATIONS

The preoperative risk for surgical complications is a function of patient factors, including medical comorbidities, medications, and behaviors, and the procedure being performed. The degree of preoperative assessment should be dictated in part by the extent of the procedure. Dermatologic procedures such as cryotherapy and shave biopsies are low risk, while flaps, grafts, MMS, and large excisions are considered higher risk. Patient risk factors may impact the surgeon's choice of surgical modality or the type of surgical reconstruction performed. Prior to the procedure, the patient should be counseled in detail on the expected postoperative course, including activity limitations, wound care, pain control, and medication management.

A thorough preoperative evaluation includes a medical history and physical examination. Diabetes, hypertension, liver failure, renal failure, immunosuppression, inherited bleeding disorders, inflammatory skin conditions, and prior radiation therapy are examples of conditions that can complicate dermatologic surgery.⁶ A thorough list of medications and supplements should be collected; many medications may impact intraoperative and postoperative bleeding. The surgeon should also assess and quantify the patient's smoking and alcohol consumption. Alcohol use and smoking may increase the risk of complications, and even minor decreases in consumption can improve postoperative results.⁶ Identifying patients with

implantable electrical cardiac devices or other implantable electric devices can guide the safe use of electrosurgery.⁷ Allergies, particularly medication reactions and prior reactions to latex or other medical materials, should be obtained. Vital signs may be obtained on the day of surgery as part of the physical examination. While there is a range of blood pressures within which dermatologic surgeons comfortably operate, one comprehensive review suggests that for patients with a systolic pressure ≤ 180 mmHg and diastolic pressure ≤ 100 mmHg and no other medical contraindications, cutaneous surgery may proceed.⁸ Higher blood pressures often warrant surgical deferment. Many surgeons rely on patient-reported history to ascertain whether a history of uncontrolled hypertension exists. Surgery should be avoided on areas of active infection or inflammation.

INTRAOPERATIVE COMPLICATIONS

Anxiety

Anxiety in dermatologic surgery results from multiple potential factors, including concern about the risks of the procedure, separation from loved ones, unfamiliar environment, loss of control, reliance on strangers, needle phobia, cosmetic concerns, and anticipation of intraoperative and postoperative pain.^{9,10} Increased levels of anxiety may have a negative impact on the patient's surgical course. The release of epinephrine into the bloodstream causes blood vessel constriction, increased heart rate, increased blood pressure and temperature, flushing, and sweating.¹¹ These physiologic changes may result in increased intraoperative and postoperative bleeding. Anxiety has also been shown to increase postoperative pain in dermatologic surgery; Chen et al. demonstrated that higher preoperative scores on two validated questionnaires, the Pain Catastrophizing Scale (PCS) and Pain Anxiety Symptoms Scale (PASS), correlate with increased pain after MMS.¹² Anxiety can also decrease patient satisfaction.¹³ In order to minimize patient anxiety, it is key to manage patient expectations and provide clear explanations before, during, and after surgical procedures.

Before surgery, patient anxiety can be decreased by a phone call discussing the diagnosis and what to expect on the day of the surgery, as well as reading written material or searching the Internet for information regarding

the procedure.¹³ Calls from physicians, as opposed to nurses or other team members, have also been shown to be effective in reducing patient anxiety.¹³ Listening to music has been demonstrated to reduce anxiety in patients undergoing dermatologic surgery, especially those undergoing surgery for the first time.¹⁴ Eating throughout the day, watching TV, bringing a guest, and engaging in small talk with the surgeon and staff during the procedure have also been shown to subjectively decrease patients' anxiety.¹³ Other potential relaxation strategies include slower breathing, biofeedback, progressive muscular relaxation, guided imagery, hypnosis, and meditation.¹⁵

Some patients may require a preoperative oral anxiolytic such as diazepam, alprazolam, or midazolam. During MMS, midazolam has been shown to offer the benefit of amnesia, reduced alertness, and reduced blood pressure with no clinically significant adverse effects.¹⁶ In patients requiring an anxiolytic, informed consent should be obtained prior to medication administration. The patient should be accompanied to their surgical appointment and should be instructed not to operate a vehicle the day of the surgery.¹⁷ The most notable side effects of benzodiazepine use include drowsiness and respiratory depression, which require intra- and postoperative patient monitoring. It is important to note that <1% of individuals taking a benzodiazepine may paradoxically experience agitation, restlessness, hyperactivity, and combativeness, and may require flumazenil for reversal of the medication.¹⁸

Reaction to Anesthesia

Pain

Given that the majority of dermatologic surgeries are performed with the patient awake, intraoperative pain management is a key concern. For instance, while MMS is typically well-tolerated, significant intraoperative pain is one of the risk factors for aborting a case prior to achieving clear surgical margins.¹⁹ Injectable local anesthesia (LA), most commonly lidocaine, is used for intraoperative pain management in dermatologic surgery. For a full discussion of LA in dermatologic surgery, see [Chapter 12](#).

LA injection itself can be painful due to needle sticks, tissue distension, and burning associated with the anesthetic itself.²⁰ Several techniques can

help minimize discomfort during the administration of LA. First, buffering lidocaine with sodium bicarbonate in a 10:1 ratio can decrease injection site pain by alkalinizing the solution toward a more physiologic range.²¹ By increasing the pH, there is a 10-fold reduction in hydrogen ion concentration, which decreases local irritation and causes a much more rapid disbursement of the anesthetic, resulting in near instantaneous nerve blockade.^{22,23} Second, various injection techniques can be utilized for pain minimization. These include using a small bore needle (most commonly a 30 gauge), injecting slowly, topical skin cooling prior to injection, using warmed anesthesia, providing distraction stimuli with pinching or vibration, injecting perpendicularly to the skin initially, using as few needle sticks as possible, and ensuring adequate depth and width of the anesthetic.^{24–28}

The use of topical anesthetics prior to LA injection can minimize both patient anxiety and pain. Topical anesthetics may decrease the pain of the needle placement, but will not impact the pain due to anesthetic infiltration. Patients should be provided instructions on safe use of the topical medication and apply the topical anesthetic under occlusion 30 to 60 minutes before arriving for their procedure.²⁹

Topical anesthetics exist in many different preparations and vehicles for delivery. There are numerous commercially available, FDA-approved topical anesthetics for use in dermatology including:

1. Eutectic mixture of local anesthetics (EMLA; Astra Pharmaceuticals, Westborough, MA), which is an oil-in-water emulsion of 2.5% lidocaine and 2.5% prilocaine.
2. Topical lidocaine products, such as Topicaine (ESBA Laboratories, Jupiter, FL), Lidoderm (Endo Pharmaceuticals, Chadds Ford, PA), and LMX (Ferndale Laboratories, Ferndale, MI).
3. Topical S-Caine peel marketed as Pliaglis (Galderma Laboratories, Fort Worth, TX), which is a eutectic mixture of 7% lidocaine and 7% tetracaine in a cream base and topical S-Caine patch marketed as Synera (Zars, Inc, Salt Lake City, UT), which is a eutectic mixture of 70 mg of lidocaine and 70 mg of tetracaine under a patented heating element that enhances delivery of the anesthetic.

All topical anesthetics have associated risks of cardiotoxicity and central nervous system (CNS) toxicity, which are heightened with prolonged application, the use of inappropriately high concentrations, and application to a large surface area. The prilocaine portion of EMLA can induce methemoglobinemia by oxidizing iron in red blood cells from the ferrous to the ferric state, impairing hemoglobin transport of oxygen.²⁹ Very young patients or patients with glucose-6-phosphate dehydrogenase deficiencies are more susceptible to methemoglobinemia.

Non-FDA-approved, pharmaceutically compounded topical anesthetics should be used with caution. These products typically contain higher concentrations of the compounded anesthetic mixtures than their FDA-approved counterparts and lack appropriate warnings or directions for use. These factors increase both the risk of adverse events and provider liability. Practitioners may wish to limit the use of topical anesthetics to those approved by the FDA, or at least those prepared by reputable compounding pharmacies.²⁹

Local Reactions

Tenderness, bruising, and edema are commonly seen after LA infiltration. Edema is often more pronounced in the thinner skin of the periorbital area or the oral mucosa and vermillion lip (Fig. 36-1). Transient motor nerve paralysis can be seen if there is anesthetic involvement of large myelinated nerve fibers. This paralysis may persist several hours after sensory nerves have returned to normal function and patients should be counseled on this potential outcome prior to the procedure.³⁰

A

B

Figure 36-1. (A) Periorbital bruising and edema after Burow's graft closure on nose. (B) Edema bullae on the hand after rotation flap closure. Reconstruction on the hand often leads to extensive swelling; this can be minimized by wrapping the hand, including the fingers and thumb to the DIP joints, to the mid-forearm with a self-adherent wrap.

Allergy/Anaphylaxis

A rare but important side effect of LAs is allergic reaction. These reactions involve either type I (immediate) or type IV (delayed-type) hypersensitivity. Most true allergic reactions to LAs are type IV reactions, also known as contact allergy. A retrospective chart review of 1819 patients found that type IV hypersensitivity to LAs has been increasing, with benzocaine (45%), lidocaine (32%), and dibucaine (23%) as the most common allergens.³¹ This phenomenon is thought to be due to an increased number of over-the-counter products containing lidocaine, resulting in unnecessary exposure and sensitization. Type IV hypersensitivity results in a local eczematous dermatitis, characterized by erythematous papules and/or vesicles that may progress to plaques and bullae; anaphylaxis is not a risk.^{31,32} The time course of type IV hypersensitivity is most commonly at least 48 hours after exposure.

In contrast, type I reactions are IgE-mediated and occur minutes to hours after exposure to an antigen. Local manifestations of type I hypersensitivity are isolated urticaria or angioedema without laryngeal involvement. Systemic manifestations, or anaphylaxis, include bronchospasm and peripheral vasodilation, presenting as tachycardia and hypotension (Table 36-1). Overall, the rate of true IgE-mediated allergy to LAs in very high-risk populations (patients reporting an LA allergy) has been found to be around 1%.³² Thus, the prevalence of IgE-mediated LA allergy in the general population is presumably significantly lower. While latex, found in surgical gloves, was previously one of the most common causes of anaphylaxis in the medical setting, widespread efforts to reduce latex exposure and sensitization have resulted in a marked decrease of the number of reactions.³³ Reports of anaphylaxis due to antibiotics, dyes, and chlorhexidine have been increasing in frequency.³³

Table 36-1. Distinguishing Reactions to Local Anesthetics in Dermatologic Surgery

	Anaphylaxis	Epinephrine Sensitivity	Vasovagal Reaction
Signs	Tachycardia + hypotension	Tachycardia + hypertension	Bradycardia + hypotension
Management	IM epinephrine 0.3–0.5 mg q5 minutes	No treatment. Nonselective beta blocker if needed.	Trendelenburg position. Atropine 0.4 mg SC if needed.

There are two classes of commercially available LAs: amides and esters. True type I allergy to amide anesthetics, including lidocaine and bupivacaine, is exceedingly rare. Most true LA allergies have been reported with ester anesthetics, including procaine, tetracaine, and benzocaine. The ester anesthetics more commonly elicit an allergic reaction because they are *p*-aminobenzoic acid (PABA) derivatives. There is no cross-reactivity between amide and ester anesthetics, but the preservative methylparaben, used as a stabilizer in multiple-dose vials of lidocaine, is structurally related to PABA. Thus, PABA and other preservatives, including sodium metabisulfite, are likely the most common cause of a reported allergy to amide LAs.^{34–36} Single-dose vials of lidocaine are available without preservatives.

If a history of type I LA allergy is documented, patients can be referred to an allergy specialist for evaluation. If an LA allergy is reported but considered low risk based on patient history, an intradermal or subcutaneous challenge can be performed in the office. This assessment is performed by injecting into the skin a 2- to 3-mm superficial bleb of a 1:1000 dilution of an LA (without epinephrine) from the opposite class as the suspected allergen. In addition, a positive control (0.10 mg/mL of histamine base) and negative control (normal saline) should be injected for comparison. The wheal and flare reaction should be evaluated at 15 to 20 minutes and, if the longest diameter of the wheal is at least 3 mm greater than the negative control, the test is considered positive. If the result of the 1:1000 dilution is negative, an increased concentration of 1:100 should also be tested before deeming the test negative. If negative, a subcutaneous challenge can then be performed with an undiluted concentration of LA.³²

It is important to be able to differentiate an anaphylactic reaction to LA from the much more common vasovagal and epinephrine reactions, which are frequently interpreted by patients as an “allergy” to LA. When a patient has systemic symptoms after the administration of an LA, a set of vitals should be taken, as well as a thorough review of systems.

With true anaphylaxis, tachycardia is coupled with hypotension. The patient may have bronchospasm, urticaria, angioedema, or other systemic symptoms such as nausea, vomiting, and diarrhea. Intramuscular epinephrine should immediately be given for anaphylaxis and the threshold for administration should be low. Treatment with antihistamines or steroids is inappropriate in cases of suspected anaphylaxis. The recommended dosing for an adult is 0.3 to 0.5 mg (this typically equals the same volume: 0.3 to 0.5

mL of a 1 mg/mL solution) of a 1:1000 solution delivered intramuscularly. This injection may be repeated every 5 minutes as needed. For a child, the recommended dosing is 0.01 mg/kg up to the adult dose of 0.5 mg. Commercially available auto-injectors deliver a preset dose of epinephrine. Dermatologic surgeons should have epinephrine solution or epinephrine auto-injectors readily available to treat suspected anaphylaxis.

If the patient is having a benign reaction to epinephrine, tachycardia with hypertension is expected. The most commonly used concentrations of epinephrine in dermatologic surgery are 1:100,000 and 1:200,000 for LA and 1:1,000,000 to 1.5:1,000,000 for tumescent anesthesia.³⁷ Even the low concentrations of epinephrine in these formulations can cause systemic effects, such as palpitations, flushing, and a feeling of panic. Epinephrine effects typically resolve spontaneously and usually do not require treatment. If needed, the recommended treatment is a non-selective beta-blocker.³² Patients can interpret the epinephrine response as anxiety or a cardiac complication, so it is important to provide reassurance as to the benign and temporary nature of this reaction. Epinephrine should be avoided in patients who have a medical history of uncontrolled hyperthyroidism or pheochromocytoma.³² Local infiltration with epinephrine has been used safely for dermatologic procedures in patients with stable cardiovascular diseases including hypertension, ischemic heart disease, arrhythmia, coronary artery disease, and heart transplantation. If there is any concern about a patient's ability to safely undergo a procedure due to cardiovascular disease, the patient's cardiologist should be consulted.³⁷

In a vasovagal reaction, bradycardia and hypotension are typically seen. This will be the most commonly encountered scenario in clinical practice. Vasovagal reaction is due to the activation of the vagus nerve in response to anxiety, fear of needles, or pain on injection, and results in heightened parasympathetic tone.³⁸ The patient will likely describe sweating, nausea, and hyperventilation.³² Patients may feel like they are about to lose consciousness (presyncope) or lose consciousness (syncope). Patients who experience syncope may lose bladder control and have rhythmic movements that can mimic a grand mal seizure.³⁹ One study revealed that young patients are more likely to experience presyncope compared with older patients, and that young males are most prone to develop true syncope.⁴⁰ If the patient is having a vasovagal response, reassurance, placing a cool towel on the

forehead, and placing the patient in Trendelenburg can alleviate the symptoms. For vasovagal reactions not responding to these measures, atropine 0.4 mg delivered subcutaneously can be considered.³² Given the risk of vasovagal reactions, it is helpful to always infiltrate LA with the patient in a supine position.

Overdose

Life-threatening systemic toxicity can potentially occur when LAs exceed their maximum dosage, or when excretion is impaired. Lidocaine has a maximum, weight-based dose of 4.5 mg/kg without epinephrine and 7.0 mg/kg with epinephrine.³⁷ Lidocaine toxicity is rare in dermatologic surgery; a 2010 study demonstrated that perioperative peak lidocaine levels during MMS do not result in serum levels approaching toxic limits, even when relatively high total lidocaine doses (up to 50 mL) are used.⁴¹ Despite this finding, toxicity has been reported as a complication of dermatologic surgery, and it is important for dermatologic surgeons to be aware of the signs, symptoms, and management of LA toxicity.^{42,43} Inadvertent intravascular administration of local anesthetic may cause systemic toxicity more commonly than gross excess of infiltrated anesthetic.^{42,43}

Overdose of lidocaine results in CNS toxicity and cardiovascular toxicity due to decreased cardiomyocyte contractility (Table 36-2). Initial signs and symptoms of lidocaine overdose occur at blood concentrations of 1 to 6 µg/mL and include perioral and digital numbness or tingling, restlessness, and lightheadedness. The patient may be increasingly talkative and describe a metallic taste in their mouth. At a concentration of 6 to 9 µg/mL, the patient may experience nausea, vomiting, twitching, tremors, blurred vision, tinnitus, and confusion. While the patient may still have a normal pulse and blood pressure, consider treating with benzodiazepines or barbiturates and ensure the airway is patent. At a blood concentration of 9 to 12 µg/mL, seizures may occur. Anticonvulsants may be used prophylactically in this situation. Additionally, initial manifestations of cardiovascular compromise may be seen, with the patient having lower than normal pulse and blood pressure. At >12 µg/mL blood concentration, the patient is at risk of coma and cardiopulmonary arrest.⁴⁴

Table 36-2. Signs of Lidocaine Toxicity

Blood Level (µg/mL)	Clinical Signs
1–6	Perioral/ digital paresthesias, restlessness, lightheadedness
6–9	Nausea, vomiting, twitching, tremors, blurred vision, tinnitus, confusion
9–12	Seizures
>12	Coma, cardiopulmonary arrest

Bupivacaine has a maximum, weight-based dose of 2.5 mg/kg without epinephrine and 3.0 mg/kg with epinephrine.³⁷ Of the non-lidocaine LAs, bupivacaine exhibits the smallest therapeutic range. Acutely elevated plasma levels may result in ventricular tachyarrhythmias and asystole, even before CNS symptoms develop.⁴⁴ If there is any concern for LA overdose of any type, anesthesia administration should be stopped and vital signs obtained. Dermatologic surgeons should have a low threshold for a transfer to a higher level of care in these cases, given the potential morbidity and mortality of anesthetic toxicity.

Digital Anesthesia

There is a historically entrenched belief that epinephrine can cause tissue ischemia and necrosis due to vasoconstriction of end arteries via alpha-1 receptors, particularly of the digits.⁴⁵ In recent years, research and reviews have invalidated this doctrine, and current evidence demonstrates that LA with epinephrine is safe for use in all clinical locations, including the digits. One study demonstrated no digital necrosis using 0.5% lidocaine with epinephrine 1:200,000 for digital anesthesia in 63 cases, including patients with peripheral vascular disease, hypertension, and diabetes mellitus.⁴⁶ Another study examined patients who accidentally injected themselves with an epinephrine pen used for anaphylaxis. No cases of digital gangrene were noted, and the epinephrine concentrations used in epinephrine auto-injectors are much higher than those used in LA for cutaneous surgery.⁴⁷ Phentolamine is a reversible nonselective alpha-adrenergic antagonist recommended for epinephrine-induced digital vasospasm, although its use after dermatologic surgery has not been reported.^{48–51}

Digital blocks can be safely performed with LA with epinephrine. The surgeon should avoid using more than 2 to 4 mL of anesthesia per digit, as the mass effect of the LA volume can potentially lead to nerve and artery compression. Circumferential ring blocks should also be avoided for this same reason.⁵² It is important to note that tubular dressings, rather than epinephrine or large volumes of LA, are the most common cause of iatrogenic digital ischemia and necrosis, due to a tourniquet effect.^{53–56}

Intraoperative Bleeding

Dermatologic surgeons must consider therapeutic antithrombotic medications, herbal supplements, inherited hemorrhagic disorders, and other comorbidities that may place a patient at higher risk of intra- and postprocedural bleeding (Table 36-3).⁷ Many patients, particularly those undergoing treatment for skin cancer, will have medical conditions that require therapy with anticoagulant and antiplatelet agents. Anticoagulants inhibit thrombin generation and fibrin formation, and include vitamin K antagonists (warfarin), indirect thrombin inhibitors (unfractionated and low–molecular-weight heparins), direct thrombin inhibitors (dabigatran, argatroban, bivalirudin, and lepirudin) and factor Xa inhibitors (rivaroxaban, apixaban, edoxaban, and fondaparinux). Antiplatelet drugs block platelet activation and aggregation, and include aspirin and clopidogrel. Both classes of medications may increase a patient’s risk of intra- and postoperative bleeding, and should be noted prior to the procedure.^{57,58}

Table 36-3. Risk Factors for Increased Intraoperative Bleeding

Medications	Supplements	Genetic Diseases	Other Patient Factors
Aspirin	Ginseng	von Willebrand disease	Uremia
Clopidogrel	Ginkgo	Hemophilia A/B (factor VIII and IX deficiency)	Liver disease
Nonsteroidal anti-inflammatory drugs	Vitamin E	Other clotting factor deficiencies	Hepatosplenomegaly
Warfarin	Fish oil		Excessive alcohol use
Heparin	Garlic		Myeloproliferative diseases/ bone marrow failure
Dabigatran, Argatroban, Bivalirudin	Dong Quai (<i>Angelica sinensis</i>)		Vitamin K deficiency
Lepirudin	Feverfew		Immune thrombocytopenia
Rivaroxaban, Apixaban	Licorice		
Edoxaban, Fondaparinux	Bilberry		
	German chamomile		
	Red clover		
	Poplar		
	Meadowsweet		
	Willow bark		
	Tamarind		
	Danshen		
	Alfalfa		
	Goldenseal		
	Green tea		

Individuals on dual antithrombotic therapy are at the highest risk for procedure-related bleeding. A 2011 prospective study of 1911 patients demonstrated that patients taking both warfarin and clopidogrel had a 40 times greater risk of bleeding complications compared to other subjects.⁵⁹ In their retrospective study of 760 patients undergoing skin surgery, another group found a significantly higher rate of bleeding complications in patients taking two or more antithrombotic medications at the time of the procedure.⁶⁰ In addition to prescription medications, herbal supplements, including ginseng, ginkgo, vitamin E, fish oil, garlic, dong quai, and others, may potentiate bleeding risks.^{61–64} Inherited hemorrhagic disorders, including von Willebrand's disease, hemophilia, and clotting factor deficiencies, should also be identified prior to a dermatologic procedure. These inherited conditions should be managed in conjunction with the patient's hematologist, given the potential need for premedication or infusions prior to the procedure. Other patient comorbidities, such as uremia, liver disease, excessive alcohol consumption, vitamin K deficiency, immune thrombocytopenia, and bone marrow failure, may further impair thrombosis.⁷

For patients with increased bleeding risk, pertinent preoperative laboratory data such as prothrombin time (PT)/International Normalized Ratio (INR) and platelet count may be reviewed. Studies suggest that it is safe to proceed with dermatologic surgery if the INR is less than 3.5 within 1 week of the operation.^{65,66} A platelet count below 50,000 is widely considered a relative contraindication to an invasive procedure. It is recommended to discontinue elective ASA and/or NSAIDs 7 to 10 days before surgery.⁶⁶ In 2012, the American College of Chest Physicians recommended continuing warfarin or aspirin perioperatively and optimizing local hemostasis during minor dermatologic procedures.⁶⁷ The current consensus is that individuals should *not* stop any medically necessary anticoagulants or antiplatelet medications prior to dermatologic surgery, as the risk of catastrophic thrombotic complications exceeds the risk of bleeding.^{58,65} There may be instances in which reduction or cessation of anticoagulation is warranted. In such cases, the decision is best made on an individual basis, with active involvement of the prescribing provider.⁶⁸ A 2015 randomized, double-blind, placebo-controlled study demonstrated that, when patients with atrial fibrillation stopped warfarin therapy prior to an elective procedure, forgoing bridging anticoagulation with low-molecular-

weight heparin was noninferior to bridging for the prevention of arterial thromboembolism and resulted in a decreased risk of major bleeding.⁶⁹ This study indicates that there may be circumstances in which anticoagulation may be stopped without increased risk to the patient.

Consideration of closure type should also be made when operating on patients with an elevated bleeding risk. Of all closure types, flaps, grafts, and partial repairs have the highest risk of bleeding.⁵⁹ Undermining is important in surgical reconstruction, but should be performed only to the degree necessary to ensure adequate tissue movement. Wide and deep undermining can cause damage to large vessels and result in extensive dead space beneath the closure, thus increasing the risk of bleeding and hematoma formation.⁷ Drain placement may be appropriate in patients who have a large postoperative wound cavity and/or a baseline bleeding propensity. Drains may be passive or active; passive drains rely on gravity to evacuate fluid, while active drains are attached to a vacuum device. In dermatologic surgery, the drain used most frequently is a passive Penrose drain. The Penrose drain may exit a wound through the inferior aspect of the suture line or from a small opening near the incision. Active drains like Jackson–Pratt (JP) or Hemovac are closed systems that connect to a reservoir and have the advantage of removing bleeding through negative pressure. Drains should be removed within 24 to 48 hours to minimize the risk of infection (Fig. 36-2).

A

Figure 36-2. (A) Penrose drain placed in a large flap closure. This passive drain needs to be placed at the most inferior aspect of the wound. (B) Jackson–Pratt drain placed in a large flap closure.

Management of Uncontrolled Bleeding Intraoperatively

Direct pressure over a bleeding vessel for 15 to 20 minutes can tamponade active bleeding, thus allowing physiologic hemostasis to take place. This method is simple and effective, though it prolongs operative time and thus is infrequently utilized.⁷ In the postoperative period, pressure dressings at the surgical site left in place for 48 hours can reduce the risk of bleeding postprocedure.

Epinephrine is often added to local anesthetics. In addition to improving the duration of action of the anesthetic, epinephrine provides transient vasoconstriction. A recent triple-blinded, randomized control trial found that the time to maximal cutaneous vasoconstriction with lidocaine containing epinephrine 1:1000 is 25.9 minutes.⁷⁰ One caveat is that some patients may be excessively sensitive to the vasoconstrictive effects of the epinephrine, resulting in an intraoperative pseudo-hemostasis that manifests postoperatively with an increased risk of bleeding or hematoma formation. If this is suspected, meticulous hemostasis of all visible bleeding should take place.⁷

Suturing techniques may also aid in achieving hemostasis. Occasionally, transection of a larger vessel (>2 mm in diameter) leads to brisk bleeding not amenable to electrosurgery. Suture ligation offers a secure and long-lasting method of hemostasis for these vessels. After identifying the bleeding vessel, both ends of the transected vessel should be clamped with curved hemostats, and each end of the vessel can be directly ligated. Alternatively, in cases where the vessel cannot be directly sutured, a figure-of-eight suture or horizontal mattress suture may be placed around the bleeding area leading to compression and hemostasis.⁷

Topical hemostatic agents are also commonly used to control intraoperative bleeding. These may be categorized as physical hemostatic

agents, chemical hemostatic agents, biologic scaffold hemostatic agents, and biologically active hemostatic agents.⁷¹ Physical hemostatic agents function to tamponade blood vessels. Chemical hemostatic agents are caustic and lead to local tissue injury and subsequent thrombus formation. Biologic scaffold hemostatic agents provide a meshwork for platelet aggregation. Biologically active hemostatic agents are purified proteins in the coagulation pathway.⁷ These materials are listed in [Table 36-4](#). For intraoperative bleeding that will not respond to electrosurgery alone, the most frequently used topical agents are absorbable gelatin (Gelfoam®), oxidized cellulose (Surgicel®), bovine thrombin (Thrombin-JMI®), and recombinant thrombin (Recothrom®).

Table 36-4. Topical Hemostatic Agents

Agent	Mechanism of Action	Advantages	Disadvantages	Formulations	Notes
Physical hemostatic agents					
Bone wax (Beeswax)	Physical tamponade to bleeding	Easy to apply	Nonresorbable, development of foreign body granulomas	Paste	Most commonly used for bleeding vessels on the calvarium
Acrylates	Rapid Polymerization to block bleeding	Nonreactive	Moderately expensive, can adhere to mucous membranes	Solution	Acetone can dissolve excess. Often used for closure of small cutaneous surgical wounds
Chemical hemostatic agents					
Aluminum chloride	Protein precipitation, thrombus formation	No risk of tattoo, low cost	Tissue irritation	Solution	Flammable even without an alcohol base
Monsel's solution (ferric subsulfate)	Protein precipitation, thrombus formation	Skin or mucosal application, ease of use	Can lead to permanent tattooing effect, tissue reaction	Solution	May interfere with tissue staining in Mohs surgery
Zinc paste	Caustic agent, thrombus formation	Theoretical tumor destruction effect	Painful to apply, extensive tissue destruction	Paste	Used in early Mohs surgery tissue fixation <i>in vivo</i>
Silver nitrate	Silver ions bind and precipitate tissue proteins	Low cost, ease of use	Tattoo risk, theoretical risk of argyria with large area application	Solution	Commonly used to treat hypergranulation tissue
Biologic scaffold hemostatic agents					
Gelatin	Meshwork to promote clot formation	Nonreactive, resorbable, low cost	Infection risks, swelling can lead to nerve or vascular compression	Foam, powders	Can be combined with thrombin
Cellulose	Meshwork to promote clot formation	Low risk of infection, resorbable	Not for graft bed or near perichondrium	Mesh, gauze, sponge	
Microfibrillar collagen	Meshwork to promote clot formation	May be removed once hemostasis achieved	Easily adheres to wet surfaces, allergic reactions	Fibrils	Bovine source
Biologically active hemostatic agents					
Thrombin	Converts fibrinogen to fibrin	Nonreactive	Risk of disseminated intravascular coagulation if introduced to large-bore vessel; expensive	Solution, powder	Works best with biologic scaffold hemostatic agent
Fibrin glue	Direct coagulation	Nonreactive	Expensive	Solution	Prepared from patient's cryoprecipitate obtained from homologous donor, or synthetic

Electrosurgery is the most commonly used method of hemostasis in cutaneous surgery ([Chapter 16](#)). This leads to thermal damage, protein coagulation, and subsequent sealing of bleeding vessels. Electrosurgery includes electrodesiccation, electrofulguration, electrosection, and electrocoagulation. Another method of hemostasis, electrocautery, does not use electricity but rather direct heat to coagulate bleeding vessels. Electrosurgery and electrocautery are key components of dermatologic surgery, but, when used in excess, can result in delayed wound healing and poor cosmesis due to thermal tissue damage and injury to the surrounding lymphovascularity.⁷

Complications Associated With Electrosurgery

Cardiac Implantable Electronic Devices

In North America alone, there are more than 250,000 new cardiac devices implanted each year.⁷² As older patients are at higher risk for both skin cancers and cardiac conditions requiring implantable electronic devices (IEDs), understanding the potential implications of electrosurgery is prudent for the dermatologic surgeon.⁷³ Electromagnetic interference (EMI) from electrosurgical devices is relatively rare, as electrosurgery in office-based settings generates relatively low electromagnetic fields. In 2000, a survey of 166 Mohs surgeons revealed a low rate of complications due to electrosurgery (0.8 cases in 100 years of surgical practice) with no significant morbidity or mortality.⁷⁴ Complications included skipped beats (eight patients), reprogramming of a pacemaker (six patients), firing of an ICD (four patients), asystole (three patients), bradycardia (two patients), depleted battery life of a pacemaker (one patient), and an unspecified tachyarrhythmia (one patient). Bipolar forceps were not associated with any complications.

Cardiac pacemakers are electronic devices consisting of a pulse generator and leads which provide electrical stimulation to cause cardiac contraction if the intrinsic heart rhythm is absent or slowed.⁷⁵ In general, pacemaker patients are classified as *dependent* or *independent*. Pacemaker-dependent patients have inadequate or even absent intrinsic rhythm, and therefore can suffer significant symptoms or even cardiac arrest after cessation of pacing.⁷⁶ As a result, patients who are pacemaker dependent are at higher risk of complications from EMI during electrosurgery. Implanted cardioverter-defibrillators (ICDs) can detect and terminate life-threatening tachyarrhythmias via high-energy shocks, and pace bradyarrhythmias. If EMI is erroneously identified as a life-threatening arrhythmia, a shock may be delivered or the ICD may respond by inhibiting cardioversion or pacing.⁷⁷ ICDs are more sensitive to EMI than pacemakers. Additionally, with poorly grounded or nonisolated electrosurgery, an implantable cardiac device can work as an indifferent plate and cause myocardial burn or arrhythmia because the delivered energy is localized to a small area.⁷⁴ Safeguards against EMI are under continuous development and include insulated coatings to limit the distance current must flow between electrodes and

protective algorithms and filters that limit nonphysiologic interference.^{72,78} As a result of the protective circuitry of modern pacemakers, complications from EMI are currently quite rare.⁷²

As office-based monopolar electrosurgical units such as hyfrecators are low powered compared to their hospital operating room counterparts, a grounding pad is not consistently required.⁷⁸ Without a grounding pad, current disperses throughout the body and results in relatively safe means of obtaining hemostasis in most patients. However, since the current travels to a distant site, there is a potential risk of EMI with cardiac IEDs. In bipolar electrosurgery, current travels through a two-electrode instrument from one electrode, through tissue, to a second adjacent electrode, completing an electrical circuit. A grounding pad is not required and electrical energy capable of interfering with an IED is minimized.⁷⁸ A recent *in vitro* study observed that monopolar electrosurgical units did not interfere with defibrillators, and affected pacemakers only when used in close proximity to the device.⁷⁹ It was concluded that these devices are safe to use in patients with defibrillators at any distance and within 2 inches of pacemakers. However, conservative guidelines advise that electrosurgery should be avoided within 15 cm of a cardiac device without consultation from an electrophysiologist.⁷⁸ The safest forms of cautery in patients with cardiac IEDs are electrocautery (heat cautery) and electrosurgery with bipolar forceps (Fig. 36-3).

Figure 36-3. (A) Electrocautery and (B) bipolar forceps. These two methods of cautery are the safest in patients with implantable electrical cardiac devices.

A magnet placed over a pacemaker will switch most demand pacemakers to an asynchronous mode.^{72,80} In this mode, the heart is paced at a fixed rate regardless of the patient's underlying rhythm.⁷⁸ This method has been used to protect patients from the inhibition of the pacemaker by EMI. When the magnet is removed, the device should revert to previous programmed pacing.

Rare case reports of pacemaker malfunction have been associated with magnet use.^{35,77} For ICDs, tachycardia detection can be disabled by magnet application without having an effect on pace mode or rate. Most ICDs will revert to prior arrhythmia detection upon the removal of the magnet. An important feature unique to ICDs is that magnet response will not affect ICD antibradycardia pacing functions.⁸⁰ Unlike pacemakers, the pacemaker function of an ICD will not be rendered asynchronous. Thus, if a patient is dependent on the intrinsic antibradycardia pacing of their ICD, they will be potentially vulnerable to bradyarrhythmias from electrosurgery-induced EMI inhibiting the pacing function.⁸⁰ Surgeons should obtain direction from a cardiologist or the patient's pacemaker/ICD clinic prior to the use of magnets due to the low but potentially significant risks.

Noncardiac Implanted Electrical Devices

Noncardiac IEDs include deep brain stimulators, spinal cord stimulators, vagal and phrenic nerve stimulators, gastric stimulators, and cochlear implants. These IEDs can also develop complications related to EMI.⁷⁸ To limit the risk of EMI, many of these devices can be turned off with an external remote control. However, some devices cannot be inactivated due to functional or medical reasons. Electrosurgery can lead to electrode heating and tissue injury around the stimulator, as well as paresthesias and electrical shocks, even if the device is deactivated.⁷² As with cardiac devices, the risk is the greatest with monopolar electrosurgical devices. If a noncardiac IED cannot be deactivated, or the surgeon is working close to the electrodes, the physician managing the device should be consulted.

Burns and Fires

Approximately 50 to 100 surgical fires occur in the United States each year, with the majority involving either electrosurgery or laser devices.^{81,82} Of these cases, one to two per year result in death.^{82,83} In dermatology specifically, electrosurgical pencil tips for coagulation are a common ignition source.⁸² Dermatologists also routinely use flammable and combustible chemicals, such as surgical dressings, drapes, and certain cleansers (i.e., isopropyl alcohol).¹⁷ Petrolatum has not been found to be flammable and can be safely used in a surgical field.⁸⁴ Supplemental oxygen has been found to be a contributing factor in 74% of all surgical fires.⁸¹

Because 90% of surgical fires are caused by monopolar electrosurgical units and laser devices, bipolar electrosurgery is the preferred method of coagulation by the Emergency Care Research Institute as a means to prevent surgical fires in situations where oxygen supplementation is required.⁸¹ In the majority of dermatologic surgery procedures, patients' oxygen can be turned off while using electrosurgery without adverse effects. All surgical personnel should be trained in fire safety procedures, including initiating a "Code Red" and knowing the location of fire extinguishers and fire alarms.

Burns can also be a major complication secondary to electrosurgery.⁸² In one survey of otolaryngologists, 324 complications from electrosurgical instruments were reported out of 99,664 cases performed in 1 year. These complications included 219 unanticipated direct burns, 48 burns secondary to current flow through a metallic retractor or instrument, 13 grounding pad burns, and 11 fires.⁸⁵ Grounding pad burns typically occur due to a pad with dry gel, an improperly sized pad, moisture under the pad, or improperly positioning the pad. Single-use grounding pads should be placed on clean, dry skin overlying a well-perfused large muscle ipsilateral and close to the surgical site.⁸²

POSTOPERATIVE COMPLICATIONS

Pain

The majority of healthy patients who undergo MMS experience mild to moderate postprocedure pain.⁸⁶ A study of 433 MMS cases demonstrated that postoperative pain was the greatest on the day of surgery and associated most strongly with flap repairs, age less than 66 years, greater number of lesions treated, and the use of narcotics for pain relief.⁸⁷ Longer-lasting LAs, particularly 0.5% bupivacaine, can be injected into the surgical site to achieve extended postoperative anesthesia. Bupivacaine has an anesthesia onset of greater than 5 minutes and duration of 4 to 6 hours, compared to lidocaine, which works in less than 2 minutes and lasts 1 to 2 hours. It is important to note that bupivacaine injected without preanesthesia with lidocaine may be painful.⁸⁸ Nerve blocks can be utilized as an alternative, or, in addition to, infiltrative anesthesia for procedures on the face, hands, feet,

and digits. Nerve blocks have the benefit of decreasing tissue swelling/distortion, prolonging anesthesia, and reducing postoperative discomfort for the patient.³⁷ For a detailed discussion of nerve block options, see [Chapter 12](#).

Management of postoperative pain with analgesics is an important consideration in dermatologic surgery. Studies have shown that a preventive, single dose of acetaminophen ≤ 1 g, ibuprofen 400 mg, diclofenac 50 mg, or etoricoxib 120 mg immediately after surgery reduces postoperative pain and opioid use.^{89,90} Options for postoperative pain control include cold analgesia with ice or gel cold packs at the surgical site, acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), opioids, or combination therapy.⁹¹ Acetaminophen remains the mainstay of pain management for minor dermatologic procedures. Doses of 500 mg to 1 g provide significant improvement in mild to moderate pain over 4 to 6 hours, up to a maximal daily dose of 3 g.⁹² At high doses of acetaminophen, rare side effects include liver failure and Stevens–Johnson syndrome. Because of risks of bleeding and hepatorenal syndrome, acetaminophen at a maximum daily dose of 2 g/day is the preferred analgesic in patients with advanced liver disease.⁹³ NSAIDs, such as ibuprofen, ketorolac, naproxen, celecoxib, and etoricoxib, are also commonly used to treat mild postoperative pain. Risks include impairment of renal perfusion, exacerbations of pre-existing renal dysfunction, weakening of gastric mucosa resulting in bleeding or perforation, worsening of underlying conditions such as hypertension, and induction of life-threatening hepatorenal syndrome in patients with cirrhosis.⁹¹

A common concern in dermatologic surgery is the effect of NSAIDs on hemostasis in the perioperative period. While it has been shown that NSAIDs do indeed increase bleeding time, the elevations are mostly within the normal range and last only hours.⁹⁴ A case series found that, in individuals taking aspirin or NSAIDs after cutaneous surgery, postoperative bleeding could not be attributed to either medication.⁹⁵ Research in the field of otolaryngology has demonstrated that the postoperative use of ibuprofen does not cause greater bleeding complications compared to acetaminophen.⁹⁶ Thus, the use of NSAIDs after dermatologic procedures likely confers a low risk for bleeding complications. A 2011 randomized controlled trial showed that the combination of acetaminophen 1000 mg and ibuprofen 400 mg offers

superior pain control compared with acetaminophen alone when given immediately postsurgery and every 4 hours thereafter for ≤ 4 doses after MMS.⁹⁷

Despite these favorable outcomes, some patients may still require opioid analgesics to control postoperative pain. Opioids are considered second-line therapy due to their adverse effect profile including nausea, constipation, and respiratory distress. Another potential risk of utilizing opioids for acute pain management is that regular use for as little as 1 week can result in dependence and withdrawal.⁹¹ Either manufactured or a-la-carte combination regimens including both an opioid (codeine, hydrocodone, or oxycodone) and nonopioid (acetaminophen, ibuprofen, or aspirin) analgesic are commonly used.

Hematoma

Hematomas are postoperative bleeding complications that occur if bleeding continues within a closed wound. Hematomas are problematic as they provide a substrate for bacterial growth leading to infections, prevent wound healing, and increase wound tension leading to possible dehiscence.⁶ Despite optimal perioperative patient management, meticulous surgical technique, and attentive hemostasis, hemorrhagic complications may still occur after dermatologic surgery procedures.⁹⁸ The risk of bleeding is the greatest in first 24 hours, and is most frequent in the first 6 hours.⁹⁹ If a hematoma is suspected, the patient should place immediate firm pressure with ice as a first step.⁹⁸ Any bleeding that does not resolve with pressure within 1 hour, or any rapidly expanding, painful subcutaneous mass should be evaluated on a more urgent basis.

Rapidly expanding hematomas indicate that there is an active bleed. They typically manifest as an enlarging, ecchymotic, fluctuant to firm mass with acute, throbbing pain (Fig. 36-4). For a rapidly expanding hematoma, the surgical closure must be partially or full opened, and the sources of bleeding identified and stopped.⁹⁹ Once hemostasis is obtained, the wound can be resutured. After postoperative bleeding is controlled, a pressure dressing should be left in place for a full 48 hours and placement of a drain may be considered.⁶

Figure 36-4. (A) Large hematoma of the cheek after rotation flap closure. (B) Stable late hematoma of the temple after primary closure.

Nonexpanding hematomas, or stable hematomas, also commonly develop within the first 48 hours. These hematomas tend to be small and do not compromise tissue viability. No immediate surgical intervention is necessary. Within 2 to 10 days, the hematoma tends to organize into a fibrotic clot, and after 14 days, the hematoma becomes fluctuant and eventually resorbs. Organized hematomas can be treated by incising with a #11 blade along the suture line or 1 cm away from the suture line, with subsequent expression of the contents. Fluctuant hematomas can be aspirated with a large-bore needle. For small hematomas, no intervention may be necessary,⁹⁹ although even small hematomas can contribute to delayed wound healing and tissue fibrosis.

Wound Dehiscence

Wound dehiscence is defined as separation of the epidermal and/or dermal edges of a wound (Fig. 36-5). The most vulnerable period for dehiscence is just after suture removal,⁹⁹ though wound dehiscence occurs in less than 1% of surgical cases. Anatomic location, but not type of closure, was

significantly associated with wound dehiscence (Fig. 36-6). Surgery on the chest, in particular, has a significantly increased risk of dehiscence when compared to other anatomic sites.⁵⁹ Causes of wound dehiscence include high wound tension, infection, necrosis, residual tumor, suture reaction, trauma to the wound, and poor wound healing secondary to anemia, hypoalbuminemia, diabetes mellitus, renal failure, and steroid use.

Figure 36-5. Wound dehiscence—epidermal and dermal separation of primary closure.

Figure 36-6. Dehiscence of wedge reconstruction on ear.

Whenever possible, wound dehiscence should aim to be prevented with proper surgical technique and detailed patient education. Removing wound tension through appropriate suturing techniques, closure design, and adequate undermining is key. Infections should be prevented and treated, and every effort should be made to remove residual tumor. The patient should be notified that the tensile strength of a surgical incision is only 10% at 2 weeks postoperatively.⁹⁹ Appropriate wound care instructions should be provided to the patient including the use of moist occlusion, gentle wound cleansing, and appropriate dressing material use. Patients should also be advised to limit certain activities or exercises that place undue tension on the wound.

The wound may be resutured in cases of early dehiscence due to premature suture removal or trauma without infection.⁹⁹ The surgeon should remove any devitalized tissue. The sutures should be removed and the wound explored if there is suspicion for hematoma. If the wound is infected or at a high risk for an infection, healing by second intention is preferred.

Skin Necrosis

Tissue ischemia is a result of decreased vascular perfusion that does not allow for adequate tissue perfusion. Ischemia can eventually result in tissue necrosis or death.⁹⁹ Black, densely adherent eschar represents tissue necrosis (Fig. 36-7).⁶ Skin necrosis is a rare complication seen in cutaneous surgery. Necrosis is often seen as a result of patient risk factors, anatomic risk factors, poor closure design (e.g., excessive tension), postoperative bleeding, or wound infection. Patient risk factors include anticoagulant use, hepatic or renal insufficiency, excessive alcohol consumption, and smoking (heavy smokers develop necrosis three times more frequently than never smokers).^{100,101} Tobacco use decreases cutaneous blood flow via nicotine (causes vasoconstriction) and carbon monoxide (impairs cutaneous oxygenation). It is recommended that patients decrease their smoking to <1 pack per day for 2 days prior to surgery and for 1 week postoperatively to minimize complications.⁶

Figure 36-7. (A) Impending necrosis of rotation flap. (B) Tissue necrosis of full-thickness skin graft. (C) Tissue necrosis of transposition flap.

Proper surgical technique also plays a major role in preventing ischemia and necrosis. Delicate tissue handling is important. The surgeon should aim to avoid macerating tissue edges; this can be achieved by using skin hooks or toothed forceps rather than serrated forceps.^{6,99} When undermining, the surgeon should avoid disrupting the dermal plexus by undermining at the appropriate depth.¹⁰² Strangulation of tissue with sutures can also lead to tissue ischemia. Elastic sutures may have a lower risk of necrosis because the suture material can expand with tissue edema.¹⁰³ The tip stitch, or half-buried mattress suture, minimizes compression on the subdermal vessels in order to minimize ischemic necrosis of vulnerable flap tips.¹⁰⁴ Mattress sutures, in contrast, may increase the risk of necrosis. Finally, prevention of hematoma, as noted above, may also prevent tissue ischemia and necrosis.

From the standpoint of closure design, high-tension closures should be avoided in order to minimize the risk of tissue ischemia.¹⁰⁵ Techniques to minimize closure tension include appropriate undermining, using plication sutures and/or dermal and subcutaneous sutures to decrease tension on the epidermal edge,¹⁰⁶ and using relaxation incisions or Z-plasties. Flaps and grafts have an increased risk of tissue ischemia compared to primary closures.¹⁰⁵ In flaps, the vascularity is based only on the pedicle supplying the tissue. The length of the pedicle correlates with the risk of flap necrosis. One study examining dermatologic surgery complications prospectively found that 4 of 241 patients (1.7%) of flap repair cases had evidence of partial flap necrosis; no complete flap necrosis occurred. The authors also found no significant association between anatomic site and flap necrosis. Graft necrosis tends to occur more frequently. In the same study, partial graft necrosis occurred in 13 of 152 patients (8.6%). Average graft loss was 50% of the total graft area.⁵⁹

The first signs of ischemia and necrosis may be seen intraoperatively. In the event of arterial insufficiency, the tissue tends to be dusky or pale and cool to the touch. If venous congestion is present, the tissue is typically dark purple and bleeds readily if pricked. In both of these settings, the surgeon should redesign or modify the closure to maximize blood flow. In the postoperative period, arterial ischemia can be reversed by early intervention, as the tissue is capable of surviving up to 13 hours. In venous congestion, the tissue progresses to necrosis much more rapidly. Serial pinpricks can be performed in the postoperative period to mitigate venous congestion. Postoperatively, tissue necrosis appears as a dusky eschar with tissue sloughing. Nonviable tissue should not be debrided given the risk of damaging underlying viable tissue. The wound should be kept moist and occluded, and patients should be counseled on the expected clinical course, including tissue sloughing and odor. Once the necrotic tissue has completely sloughed off, healing by second intention or surgical intervention can be considered. No surgical closure should be attempted with devitalized tissue still present in the wound bed.

Infection

Wounds can be classified (I to IV) according to the site and status of the wound preoperatively (Table 36-5).¹⁰⁷ While there are differing definitions of localized surgical skin infections, the Centers for Disease Control and Prevention states that a superficial surgical site infection (SSI) can be diagnosed if it involves skin, subcutaneous tissues, or muscle above the fascial layer at the incision site, occurs within 30 days of surgery, and at least one of the following is present:

Table 36-5. Wound Classification Based on 1985 Centers for Disease Control Classification of Wounds

Class	Skin Condition	Body Location/Surgical Technique	Antibacterial Recommendations
I	Clean	Sterile procedure	No prophylaxis
II	Clean contaminated	Oral cavity, nasal mucosa, perineum, axilla; sterile procedure	Prophylaxis only if immunocompromised
III	Contaminated	Traumatic wounds, nonpurulent inflammation; nonsterile procedure	Therapeutic antibacterials
IV	Infected	Gross contamination, devitalized tissue, foreign body contamination	Therapeutic antibacterials

- Purulent discharge from the incisional wound.
- Organisms are isolated on culture of aseptically obtained wound fluid or tissue.
- One or more of the following is present: pain, tenderness, localized swelling, redness, or heat.
- The surgeon deliberately reopens the wound (unless culture of the incision is negative)
- The treating doctor diagnoses a superficial incisional SSI.^{107–109}

The overall rate of infection is very low in dermatologic surgery, ranging from 0.7% to 3.5%.^{59,110,111} A wound infection develops when sufficient pathogenic bacteria contaminating the wound overcome the local tissue defenses and host response.¹¹² Postoperative surgical wound infections may have a significant effect on the outcome of a dermatologic surgical procedure, including the final cosmetic appearance of the wound.¹¹³ Higher risk procedures include those below the knee or in the groin area, wedge excisions of the lip and ear, flaps on the nose, and all skin grafts.^{107,111,112,114}

Intrinsic factors that place a patient at higher risk of infection include coincident remote site infections or colonization, cigarette smoking, diabetes,

systemic immunosuppression, obesity, extremes of age, and poor nutritional status.¹⁰⁷ The most common bacteria found in wound infections (in order of decreasing frequency) are *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Enterococcus* species, *Escherichia coli*, and *Pseudomonas aeruginosa*.¹⁰⁸ It is commonly thought that *P. aeruginosa* is the main pathogenic organism in infections of the ear after dermatologic surgery; however, it has been shown that *S. aureus* is actually the most common bacteria cultured from SSIs on the ear.¹¹⁵ *Enterococcus* and *E. coli*, as well as other gram-negative bacteria, are commonly cultured from groin and lower extremity infections.^{107,108} Most bacterial SSIs are a result of the presence of bacteria on the patients' skin or mucosa.¹¹⁶ Other potential sources of bacterial contamination include colonized surgical personnel, surgical suite fomites, adhesive dressings, and contaminated disinfectant solutions.¹¹⁷

Signs and symptoms of wound infection usually develop within 4 to 8 days postoperatively and are characterized by pain, erythema, tenderness, and purulent discharge (Fig. 36-8). Cellulitis occurs when the infection spreads into the surrounding skin and soft tissue beyond the incision and manifests as swelling, warmth, expanding redness, and pain. Infection is a clinical diagnosis based on the patient's signs and symptoms. Wound cultures may guide treatment, but a positive culture does not necessarily indicate active infection. Normal skin flora may be seen in wound cultures, and chronic wounds (>6 weeks) will almost universally be contaminated with bacteria.

Figure 36-8. (A) Superficial surgical site infection of primary closure on arm. (B) Surgical site infection of primary closure on the infra-auricular with underlying abscess. (C) Expressing pus from an abscess on the arm.

Severe Infections

Special considerations must be made when treating methicillin-resistant *S. aureus* (MRSA). MRSA can be hospital- or community-acquired; hospital-associated strains often exhibit multiple antibiotic resistance, while community-associated strains are often only resistant to methicillin.¹¹⁸ To diagnose MRSA, bacterial culture with antibiotic sensitivity should be obtained. MRSA should be suspected if SSI persists despite empiric antibiotic treatment. Treatment includes surgical drainage when an abscess is present and an appropriate antibiotic regimen consisting of either trimethoprim/sulfamethoxazole DS twice daily for 7 to 10 days, clindamycin 300 mg PO four times daily for 7 to 10 days, or doxycycline 100 mg twice daily for 7 to 10 days.¹¹⁷ Culture sensitivities and clinical response will subsequently determine whether alternative or additional antibiotic agents are necessary. The rates and antibiotic sensitivities of MRSA vary by region.

Necrotizing fasciitis occurs when pathogens extend beyond the skin and subcutis and involve the superficial fascia. The infection is usually polymicrobial, though *Streptococcus pyogenes* has been implicated in many cases.^{119,120} While early necrotizing fasciitis can be difficult to distinguish from cellulitis, red-flag symptoms include exquisite pain, violaceous bullae, eschar, necrosis, and decreased sensation.¹²¹ Necrotizing fasciitis is exceedingly rare following dermatologic surgery, but has been reported after excision of a melanoma.¹²² Inpatient management with surgical debridement, broad-spectrum antibiotics, and hemodynamic support is required.¹¹⁷

Very rarely, staphylococcal wound toxic shock syndrome can cause early fever and systemic signs following a surgical procedure.^{123,124} In these cases, the wound is often benign in appearance. Erythroderma tends to occur early with subsequent desquamation. Fever, hypotension, abnormal hepatic and renal blood studies, and diarrhea are early systemic findings. The incision should be opened and cultured, and the patient should begin antistaphylococcal treatment.¹²⁵

Infection Prevention. Many techniques exist to prevent infection in dermatologic surgery. Patient hygiene should be encouraged. Based on data from the general surgery literature, patients are often advised to shower before dermatologic surgery, despite a lack of data showing a clear benefit in cutaneous procedures.¹²⁶ A large systematic review recently illustrated no evidence of benefit for preoperative showering or bathing with chlorhexidine over other wash products.¹²⁷ If possible, surgery on areas of active infection or active inflammatory skin disease should be avoided. When it is necessary to remove hair, the existing evidence suggests that clippers are associated with fewer SSIs than shaving with razors.^{128,129}

Antiseptic agents are an initial line of defense against SSIs. The widely accepted technique for cleansing the skin prior to cutaneous surgery is to scrub with antiseptic in concentric expanding circles until a wide region is cleansed around the surgical site. This technique minimizes the chance of spreading pathogens from the periphery into the procedure site, and provides a sterile zone around the site where surgical instruments may contact without becoming contaminated.¹¹⁷

Commonly used surgical antiseptics include isopropyl alcohol 70%, povidone–iodine, and chlorhexidine gluconate with or without alcohol.

Isopropyl alcohol acts by denaturing microbial proteins and has a rapid onset. However, isopropyl alcohol is flammable and can irritate the skin.¹⁰⁸ Povidone–iodine acts through oxidation and substitution by free iodine. It has a broad spectrum of antimicrobial activity and a rapid onset of action, typically within minutes, but must be left on the skin to have sustained activity.¹⁰⁹ Povidone–iodine is inactivated by blood and sputum, can cause a contact allergy, and has been known to cause hypothyroidism in neonates when there is chronic maternal use.¹⁰⁸ Chlorhexidine gluconate disrupts cell membranes and has excellent gram-positive coverage and good gram-negative and viral coverage, but poor mycobacterial and fungal coverage.^{108,109} Chlorhexidine binds to the stratum corneum and maintains antimicrobial activity for longer than 6 hours even when wiped off. Chlorhexidine can cause keratitis and cochlear damage in the setting of a ruptured tympanic membrane, so the use around the eye and ears should be performed with caution.^{108,109}

Some research supports the efficacy of intraincisional antibiotics (nafcillin or clindamycin) to prevent postoperative wound infections when compared with placebo. The benefits of intraincisional antibiotic prophylaxis include immediate delivery to the surgical site, ease of use, enhanced compliance, and low cost compared with other routes of delivery.¹¹³ The limitations of this technique include the risk of patient allergy, and theoretically increased bacterial resistance. Postoperative topical antibiotic preparations have not been found to differ from petrolatum ointment in healing time or infection rate for clean surgical wounds.¹³⁰ Allergic contact dermatitis (ACD) is a well-documented adverse effect of topical antibacterial agents. For this reason, topical antibacterial preparations are not commonly indicated for routine use after dermatologic surgery procedures.

A few controversies exist in infection prevention techniques in dermatologic surgery. First, while many surgeons wear sterile gloves for dermatologic procedures such as excisions and MMS, a 2010 study suggested that clean, nonsterile technique is adequate for achieving an exceedingly low SSI rate.¹³¹ More recent studies also demonstrated no difference in infection rate when sterile versus nonsterile gloves are used during MMS resection and reconstruction, with the use of nonsterile gloves resulting in significant cost savings.^{132,133}

Second, a common practice is to use one sterile set of instruments for tumor removal and a different sterile set for the repair during MMS. One recent study suggested that using a single set of sterile surgical instruments for both removal and repair stages of MMS maintains SSI rates within an acceptable range and leads to cost savings.¹³⁴ However, further investigation is needed before this technique is broadly adopted, given concerns for SSI and potential issues of tumor spread from using a single set of instruments during MMS. Moreover, many clinicians use a minimalist instrument set for the performance of MMS (blade and forceps), while reconstructive surgical sets are generally much more involved. Thus, in practice, it is not clear whether this using the same instrument set would result in any significant cost or time savings.

Antibiotic Prophylaxis

Indiscriminant oral antibiotic prophylaxis is discouraged in cutaneous surgery, in light of the risk of possible adverse effects, antibiotic cost, and the potential for contributing to the development of antibiotic-resistant bacteria.¹⁰⁷ Antibiotics are associated with numerous adverse side effects ranging from mild gastrointestinal (GI) upset to serious cutaneous reactions such as toxic epidermal necrolysis, acute hepatitis, nephrotoxicity, and *Clostridium difficile* colitis.¹⁰⁸ Not only is the incidence of community acquired MRSA on the rise, but antimicrobial resistance to viridans group streptococci, one of the major causes of infective endocarditis (IE), is also increasingly reported in the literature.^{108,135}

An advisory statement published in 2008 provided an update on the indications for antibiotic prophylaxis in dermatologic surgery for the prevention of SSI, IE, and hematogenous total joint infection (HTJI).¹¹⁴ This statement incorporated recommendations from the 2007 American Heart Association (AHA) guidelines for endocarditis prophylaxis, as well as the 1997 and 2003 American Dental Association (ADA) and American Academy of Orthopaedic Surgeons (AAOS) advisory statements regarding prophylactic antibiotics in preventing HTJI following dental procedures.^{136–138}

If a dermatologic procedure involves the oral mucosa or infected skin (Class II), patients with certain cardiac conditions (Table 36-6) or joint

conditions should receive prophylactic antibiotics to prevent IE and HTJI, respectively. High-risk indications for HTJI include a history of total joint replacement within the preceding 2 years, previous prosthetic joint infections, and certain comorbidities with a history of joint replacement at any point in time.¹¹⁴ High-risk comorbidities include insulin-dependent (type I) diabetes, malignancy, immunosuppression, HIV, malnourishment, and hemophilia. Finally, antibacterial prophylaxis may be warranted for high-risk cardiac and whole joint prosthesis patients undergoing dermatologic surgery in sites that are associated with higher rates of infection (below the knee, in the groin, flaps on the ear and nose, wedge excisions, or grafts). These high-risk dermatologic surgery patients may also receive preoperative antibiotic prophylaxis to prevent SSI, but no guidelines exist delineating if and when this is warranted.¹⁰⁷

Table 36-6. Cardiac Conditions for Which Antibiotic Prophylaxis Is Recommended to Prevent Infective Endocarditis in Surgery Involving the Oral Mucosa or Infected Skin

Prosthetic cardiac valve or prosthetic material used for cardiac valve repair
Previous infective endocarditis
Congenital heart disease (CHD) from the following:
■ Unrepaired cyanotic CHD, including palliative shunts and conduits ■ Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure ■ Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
Cardiac transplantation recipients who develop cardiac valvulopathy

A suggested antibiotic prophylaxis regimen for dermatologic surgical procedures that breach oral mucosa or involve infected skin of high-risk

patients is shown in Table 36-7.¹¹⁴ The same 2008 advisory statement suggested antibiotic prophylaxis regimens for patients at increased risk of SSIs (Table 36-8).¹¹⁴ Finally, in the setting of endocarditis prophylaxis, the AHA advises that an antibiotic should be given 60 minutes prior to a procedure, but may be given up to 2 hours after the procedure, if it is inadvertently not given before the procedure.¹³⁵ The ADA and AAOS recommended antibiotics to be administered 60 minutes prior to the procedure.¹¹⁴

Table 36-7. Suggested Antibiotic Prophylaxis Regimens for Dermatologic Surgical Procedures that Breach the Oral Mucosa or Involve Infected Skin in Patients at High Risk for Infective Endocarditis or Hematogenous Total Joint Infection

Surgical Site	Medication Restrictions	Agent	Adult Dose
Nonoral	No PCN allergy	Cephalexin	2 g PO
		OR Dicloxacillin	2 g PO
Nonoral	Patient with PCN allergy	Clindamycin	600 mg PO
		OR Azithromycin/clarithromycin	500 mg PO
Nonoral	Patient unable to take PO medication	Cefazolin/ceftriaxone	1 g IM/IV
Nonoral	Patient unable to take PO medication and has PCN allergy	Clindamycin	600 mg IM/IV
Nonoral (skin infected and pathogen known)	No PCN allergy	Antibiotic specific for pathogen	
Oral (breach of oral mucosa)	No PCN allergy	Amoxicillin	2 g PO
Oral	Patient has PCN allergy	Clindamycin	600 mg PO
		OR Azithromycin/clarithromycin	500 mg PO
Oral	Patient unable to take PO medication	Cefazolin/ceftriaxone	1 g IM/IV
		OR Ampicillin	2 g IM/IV
Oral	Patient unable to take PO medication and has PCN allergy	Clindamycin	600 mg IM/IV

IM, intramuscular; IV, intravenous; PO, by mouth; PCN, penicillin.

Table 36-8. Suggested Antibiotic Prophylaxis Regimens for Patients at Increased Risk of Surgical Site Infection

Surgical Site	Medication Restrictions	Agent	Adult Dose
Wedge excision of lip or ear; flaps on nose; all grafts	No PCN allergy	Cephalexin OR Dicloxacillin	2 g PO 2 g PO
Lesions in groin and lower extremities	No PCN allergy	Cephalexin OR TMP-SMX-DS OR Levofloxacin	2 g PO 1 tablet PO 500 mg PO
Wedge excision of lip or ear; flaps on nose; all grafts	Patient w/ PCN allergy	Clindamycin OR Azithromycin/clarithromycin	600 mg PO 500 mg PO
Lesions in groin and lower extremities	Patient w/ PCN allergy	TMP-SMX-DS OR Levofloxacin	1 tablet PO 500 mg PO
Wedge excision of lip or ear; flaps on nose; all grafts	Patient unable to take PO medications	Cefazolin/ceftriaxone	1 g IM/IV
Lesions in groin and lower extremities	Patient unable to take PO medications	Ceftriaxone	1–2 g IV
Wedge excision of lip or ear; flaps on nose; all grafts	Patient unable to take PO medications; has PCN allergy	Clindamycin	600 mg IM/IV
Lesions in groin and lower extremities	Patient unable to take PO medications; has PCN allergy	Clindamycin and gentamicin	600 mg/2 mg/kg IV

IM, intramuscular; IV, intravenous; PO, by mouth; PCN, penicillin; TMP-SMX-DS, trimethoprim-sulfamethoxazole, double strength.

Treatment

Once an SSI is diagnosed, wound culture should be obtained and the patient should be started on empiric antibiotics based on the most likely causal organism. A 7-day course of oral antibiotics is sufficient treatment for most SSIs. In the majority of cases, empiric treatment with an antibiotic that has activity against *S. aureus* is effective. This treatment includes either a first-generation cephalosporin, such as cephalexin 250 to 500 mg PO three or four times daily, or a penicillinase-resistant penicillin, such as dicloxacillin 250 to 500 mg PO twice, three or four times daily.¹¹⁷ Antibiotic therapy should be modified, if necessary, based on culture and sensitivity results. If an abscess is present, it should be drained in a sterile setting under LA. Some or all sutures may need to be removed to permit adequate drainage. The wound then may either be packed with sterile gauze or allowed to remain open to drain. The patient should be seen for close follow-up to ensure resolution of the infection and to monitor for future complications.

Nerve Damage

Sensory Nerves

Cutaneous nerves are commonly transected during dermatologic surgery. As a result, patients frequently experience paresthesias at the procedure site. Given that most areas on the skin have diffuse sensory innervation, and

sensory nerves often regenerate, there are rarely significant permanent deficits from cutaneous surgery. Patients should be counseled preoperatively about risk of paresthesias at the surgical site, and that normal sensation usually returns within 18 months. Occasionally, complete sensation never returns. Areas most prone to sensory nerve injury and appreciable deficits are the digits, forehead, and scalp. In particular, procedures that require deep tissue removal or dissection risk permanent damage to the branches of the trigeminal nerve on the face, with subsequent sensory loss.

Motor Nerves

Injury to motor nerves can result in more severe consequences than damage to sensory nerves. Though rare, damage to motor nerves can cause significant functional impairment. While many of the muscles of the head and neck have significant redundancy in innervation, there are specific motor nerve “danger zones” that are most at risk during dermatologic surgery. Overall, the risk of motor nerve damage in dermatologic surgery is very low, but patients need to be counseled preoperatively when operating in high-risk locations. Surgeons also need to be aware that significant individual variability exists in the anatomic course of nerves. Additionally, patients with tissue atrophy, such as seen with normal aging or HIV lipoatrophy, will have motor nerves coursing in a more superficial plane. If motor nerve damage occurs, it may be temporary (neuropraxia) or permanent. It is prudent to consult with the appropriate specialty (generally neurology or otolaryngology) early to optimize management after motor nerve damage. The nerves at the greatest risk for injury during cutaneous surgery are the temporal and marginal mandibular branches of the facial nerve and the spinal accessory nerve.⁴⁴

The temporal branch of the facial nerve is the most commonly injured nerve in facial surgery. When damaged, it will lead to ipsilateral brow ptosis secondary to paralysis of the frontalis muscle (Fig. 36-9).¹³⁹ The nerve branches off the facial nerve trunk within the parotid gland and courses superficially across the zygomatic arch within the innominate fascia (a plane deep to the SMAS and superficial temporal fascia), and crosses the temple with little overlying subcutaneous fat.¹⁴⁰ If nerve damage is permanent, this complication can be addressed with a direct or indirect brow lift. Over time, patients may develop a compensatory brow elevation on the contralateral side of injury.¹³⁹

Figure 36-9. Injury to the temporal branch of the facial nerve resulting in the inability to raise the right brow due to frontalis muscle paralysis.

The marginal mandibular branch of the facial nerve traverses the mandible near the facial artery and vein, covered only by skin and thin platysma muscle. While the nerve is normally located approximately 1 to 2 cm below the mandible, in individuals with lax or atrophic tissues (as seen with aging), the branches can be as low as 3 to 4 cm below the mandible.¹⁴¹ This nerve innervates the lip depressors, and damage presents clinically as asymmetric facial expressions and mouth function compromise. This asymmetry and lip imbalance are readily noticeable during opening of the mouth (Fig. 36-10).¹⁴² The marginal mandibular nerve is at risk during liposuction of the jowls and neck dissections, as well as after deoxycholic acid injections for submental fat.^{143,144} The buccal and zygomatic branches are deeper, with more collateral innervation, and are at less risk of damage when compared to the other branches of the facial nerve.

A

B

Figure 36-10. Marginal mandibular nerve paralysis after neck dissection, with injury on the right side: (A) At rest; (B) smiling showing compensation on the left side.

Finally, damage to the spinal accessory nerve results in a winged scapula due to trapezius muscle palsy. This palsy results in dropping of the shoulder

girdle inferiorly and laterally along with flaring of the wing of the scapula and loss of abduction of the arm.⁴⁴ The spinal accessory nerve exits behind the sternocleidomastoid (SCM) muscle at the junction of the upper and middle third of the SCM, then courses across the posterior triangle of the neck. It primarily innervates the trapezius and partially innervates the SCM. Inadvertent transection can occur during procedures in the posterior triangle of the neck, including radical neck dissection, lymph node dissection, and extensive cyst or tumor resection.

Suture Reaction

All sutures elicit some degree inflammatory response when embedded in tissue, but the response is variable. Several factors contribute to tissue reactivity including suture material, configuration, caliber, and absorbability. The degree of inflammatory response to biologic sutures (i.e., fast, chromic, or plain gut or silk) is much higher than that seen with synthetic sutures (i.e., nylon or polypropylene).¹⁴⁵ Additionally, monofilament configurations of suture are thought to lead to less reactivity when compared to a multifilament configuration. Immediate postoperative suture reaction is characterized by erythema and tenderness of the skin. When suture reaction develops later in the postoperative course, it often presents as a “spitting suture,” where there is residual suture material in the skin and/or an inflammatory foreign body reaction (Fig. 36-11). Spitting sutures tend to occur 1 to 4 months postoperatively and present as a focal, aseptic pustule at the site of a buried suture. One study examined 140 patients and found that suture reaction was significantly less with poliglecaprone-25 (3.1%) as compared to polyglactin-910 (11.4%).¹⁴⁶ Surgical techniques that can help prevent spitting sutures include placing absorbable sutures deep in the dermis, utilizing the set-back suture technique, cutting sutures at the knot, and closing wounds with minimal tension.^{146–148} To treat a spitting suture, the site can be nicked with an #11 blade and the purulence expressed and residual suture removed.

Figure 36-11. (A) Immediate suture reaction presenting as erythema and edema at 1 week postoperative. (B) Late suture reaction to deep sutures presenting as sterile pustules along the closure line at 6 weeks postoperative. (C) Late suture reaction presenting as small ulceration along suture line.

Contact Dermatitis

ACD represents a type IV hypersensitivity reaction, and ranges in presentation from mildly pruritic erythema to intensely pruritic vesicular, bullous, or indurated plaques. The presence of erythema and induration around a postoperative surgical site may initially raise concern for SSI, but the clinical appearance of a contact dermatitis differs from infection. Contact dermatitis often occurs away from the wound edges, may have an angulated appearance, lacks purulence and tenderness, and is frequently itchy (Fig. 36-12). ACD may be caused by any material in dermatologic surgery, including surgical antiseptics and wound dressings. Antiseptics used to prepare the surgical site are common causes of contact dermatitis. Most commonly, this is seen with povidone–iodine, but a similar reaction has also been reported to chlorhexidine.¹⁴⁹ Postoperatively, fixatives (e.g., benzoin and mastisol), dressings (e.g., colophony), and antibiotics (e.g., bacitracin and neomycin) are potential sources of ACD. If a patient has a history of ACD, it is

recommended that white petrolatum be used instead of any potential allergy-inducing products.¹⁴⁹ Contact dermatitis will frequently resolve spontaneously once the implicated agent is removed from the skin. However, in cases of severe reactions that present with blistering or severe pruritus, topical or even systemic steroids may be helpful.

Figure 36-12. Contact dermatitis presenting as angulated erythema corresponding to the location of adhesives. (A) Mild erythema and itching. (B) Severe reaction with blisters and edema.

Abnormal Wound Healing and Scarring

Excessive Granulation Tissue

Excessive granulation tissue is considered a type of abnormal wound healing and is often seen in wound healing by second intention.¹⁵⁰ Associated factors include wound site, prolonged inflammation, an imbalance in matrix metalloproteinases, and excessive angiogenesis. While a modest amount of granulation tissue is considered favorable in wound healing by second intention, too much granulation tissue inhibits wound healing by preventing fibroblast proliferation. Granulation tissue appears beefy red and friable, and may extend above the level of normal skin. Management of excessive granulation tissue includes destruction with silver nitrate, laser ablation, cautery, curettage, or shave removal of the tissue. Medium- to high-potency topical corticosteroids have also been used with success.^{150,151}

Scarring

Scarring after skin cancer surgery can profoundly affect psychosocial functioning, especially when scars are located on the head and neck.¹⁵² For

many patients, the success of a surgical procedure is often tied to the aesthetic appearance of the final scar. Surgical scars tend to have a variable presentation, and may have multiple features that must be addressed for optimal scar reduction. Scars may be characterized by abnormal erythema or pigmentation, firmness, visibility, contour irregularity, and other negative factors. Additionally, the position, location, age of the scar, and skin type of the patient should be considered. For many surgical scars, time will resolve many of the adverse features. Laser therapy with multiple different energy modalities has been shown to improve scar features.^{153,154} Dermabrasion is another method for treating surgical scars, and is particularly useful on sebaceous nasal skin.¹⁵⁵ Surgical scar revision may be attempted if the scar is not exhibiting favorable characteristics for long term. Multiple techniques may be utilized, including scar excision with linear closure, Z-plasty, W-plasty, and geometric broken line closure.¹⁵⁵ Surgical scar revision techniques are addressed in detail in [Chapter 35](#).

Hypertrophic/Keloid Scars. Hypertrophic scars and keloids are two forms of abnormal wound healing characterized by local fibroblast proliferation and excessive collagen production in response to cutaneous injury. Hypertrophic scars tend to remain confined to the scar line, whereas keloids extend beyond the margin of the scar. Hypertrophic scars often arise earlier than keloids, usually within 4 weeks postoperatively. Keloids may develop months to a year after trauma or surgery.¹⁵⁶ Hypertrophic scars can regress without intervention, whereas keloids do not, and indeed frequently recur after surgical removal. Keloids are more common on the chest and back of darker-skinned patients, and are often also seen at the sites of wounds healing by second intention.¹⁵⁷ In contrast, spread scars tend to be more atrophic, with thin, fragile tissue centrally. Spread scars occur in areas under high tension, high use (shoulders, chest, back), and in the context of infection or dehiscence.

The first-line treatment for hypertrophic scars and keloids is intralesional steroid injections.¹⁵⁸ While this approach is considered largely effective, it may be associated with cutaneous atrophy, pigmentary alteration, and telangiectasias.¹⁵⁹ Re-excision with the addition of pressure therapy, postoperative radiation, and intralesional steroid injections has also been performed with success for keloids,^{160,161} and one study has demonstrated an effective combination of re-excision and closure with the set-back suture

coupled with postoperative radiation.¹⁶² Finally, silicone gel sheeting, 585- or 595-nm pulsed-dye laser, cryotherapy, intralesional 5-fluorouracil (5-FU), interferon alfa-2b injections, fractional nonablative lasers, and ablative laser treatment may also be of benefit for keloids.^{163–168}

Suture Track Marks. Track marks are often seen when epidermal sutures are left in place longer than necessary or are placed too tightly (Fig. 36-13).¹⁰⁴ Postoperative edema tends to exacerbate track marks due to increased tension on epidermal sutures. To prevent track marks, sutures should be removed as early as possible, wound tension should be maximally decreased by performing adequate undermining, buried dermal or subcutaneous sutures should be used for tension reduction, and sutures of appropriate size should be used for a given anatomic location. A recent randomized controlled trial found the set-back suture to be superior to the buried vertical mattress suture for postoperative scar cosmesis.¹⁴⁸ Tissue adhesives or adhesive strips may also be used in place of epidermal sutures in order to prevent track marks as long as dermal sutures have been placed to reduce tension.¹⁶⁹

Figure 36-13. Spread surgical scar.

Trapdoor Phenomenon

The trapdoor phenomenon, or pin-cushioning, is a contour irregularity due to scar elevation above the surrounding skin surface. This abnormal scarring is most frequently seen in flaps on the nose and upper cutaneous lip ([Fig. 36-14](#)). Irregular flap contour may be due to several factors, including lymphatic or venous obstruction, postoperative ischemia, resolving hematoma, scar hypertrophy, excessive subcutaneous fat or flap tissue, and scar contracture. The deformity typically appears within 3 weeks to 6 months after surgery and can be prevented with optimal flap design, wide undermining of the recipient site, squaring of the corners (versus circular trimming), appropriately thinning the flap, and the judicious use of dermal sutures to re-approximate muscle and dermis. Potential treatments include surgical revision by lifting and thinning of the flap, intralesional steroid injection, and dermabrasion. Over time, improvement may be seen without intervention. [170,171](#)

Figure 36-14. Pin-cushioning or trapdoor deformity of transposition flap on the nose.

Free Margin Retraction

Free margins are anatomic areas where the skin surface remains unattached to the surrounding tissue. Common free margins on the face are the eyelid, helical rim of the ear, alar rim of the nose, and the vermilion lip. Because they offer little resistance to tension created by surgical reconstruction or scar contracture, free margins are vulnerable to distortion ([Fig. 36-15](#)).

A

B

Figure 36-15. Contracture of a free margin resulting in (A) ectropion after lower blepharoplasty and (B) alar retraction after interpolated flap necrosis.

Disruption of these natural contours is both aesthetically displeasing and functionally significant. Ectropion may result in difficulty closing the eyelids with subsequent dry eyes and corneal irritation, alar rim retraction can cause

nasal valve obstruction, and eclabium can lead to challenges when creating a tight oral seal.

To prevent these complications, surgical closures must be designed to minimize tension on the free margin; this is often achieved by orienting closure tension vectors perpendicular to the free margins to avoid “pulling” the free margin out of position.¹⁷² Cartilage grafts may be used to prevent alar rim retraction, and Frost sutures may be used to prevent ectropion in the immediate postoperative period, though they cannot compensate for poorly designed closures.¹⁷³ Caution should be used when using second-intention healing or when placing skin grafts in locations near a free margin, as clinically significant contraction may occur. Treatment of free margin retraction includes intralesional steroids and scar revision.

SEVERE POSTOPERATIVE RISKS OF DERMATOLOGIC SURGERY

The incidence of catastrophic complications in dermatologic surgery is exceedingly low, but providers should be aware of potential emergent situations so that early detection may mitigate adverse outcomes. Such emergent scenarios include anaphylaxis from type I immune hypersensitivity reactions, cardiac arrhythmias from electrosurgery, and local anesthetic/lidocaine toxicity.⁴⁴

Life-threatening air embolism resulting from the removal of large scalp tumors has been reported in the dermatologic surgery literature.^{174,175} Positioning the patient flat during surgery, so as to minimize a pressure gradient, and using airtight dressings between MMS stages helps to prevent this complication.⁴³ If faced with a potential air embolism, the dermatologic surgeon should immediately refer the patient to a higher level of care, due to the risk of permanent neurologic insult.

Venous thromboembolism—including deep vein thrombosis and pulmonary embolism—is another reported complication after MMS.^{176,177} Most cases of DVT and PE after dermatologic surgery have occurred in patients with underlying hypercoagulability who have discontinued anticoagulation perioperatively. Treatment includes anticoagulation, inferior vena cava filters, thrombolysis, and compression stockings.⁴³

RISKS TO THE DERMATOLOGIC SURGEON AND OTHER HEALTH CARE PERSONNEL

Surgical Smoke

Surgical smoke or plume is the gaseous byproduct produced by the destruction of human tissue by electrosurgery or other procedures.¹⁷⁸ It is estimated that a Mohs surgeon who performs 1000 cases per year receives approximately 50 hours of continuous smoke exposure per year.¹⁷⁹ Surgical smoke and plume generated by electrosurgery and lasers have been demonstrated to harbor live viruses and bacteria in addition to hazardous chemicals. As a result, the potential exists for infection, carcinogenesis, and pulmonary damage from surgical smoke exposure.¹⁸⁰ Surgeons' exposure to smoke is more concentrated than for other perioperative personnel because they are closest to the tissue destruction. The use of standard surgical masks offers little to no protection against inhalation of surgical smoke. The best protection for surgical personnel is the use of smoke evacuator units during electrosurgery. Integrated cautery and smoke evacuator units are convenient and easy to use, decrease the need for extra staff, and improve patient comfort by aiding in the removal of unpleasant odor of surgical smoke.

Sharps Injuries

The CDC estimates that more than 380,000 sharps exposures occur annually.¹⁸¹ Sharps injuries pose an occupational hazard to dermatologists because of the large number of procedures they perform. A 2013 cross-sectional survey of practicing dermatologists and trainees revealed that 85.1% of 336 responders had experienced a needle stick injury during their career. Importantly, 64% of respondents experienced a sharps injury that they did not report.¹⁸² The most frequently cited reason for not reporting an injury was the belief that the patient was a low risk for a hematologically spread infectious disease. A similar 2016 survey of dermatology residents showed that, of 351 responders, 76% had a sharps injury during training and 34% went unreported.¹⁸³ Given the risk of communicable diseases such as hepatitis B virus (HBV), hepatitis C virus (HCV), and human

immunodeficiency virus (HIV), it is important to promptly report injuries to occupational health services so that appropriate baseline and follow-up testing can be informed, and prophylactic medication administered. Improving the ease of access to reporting systems, ensuring anonymity, and encouraging ongoing sharps safety training may increase the prevalence of reporting.¹⁸² In addition, continued efforts to decrease the stigma associated with medical errors are essential.

To prevent sharps injuries in dermatologic surgeons and other team members, several preoperative, intraoperative, and postoperative techniques can be employed.¹⁸⁴ Preoperatively, one should wear protective devices (gloves, masks, protective eyewear, and protective footwear). Intraoperatively, it is important to practice safe handling and transferring of sharp instruments, minimize the use of sharps, and protect from backsplash injuries. When treating patients with known infectious hepatitis or HIV, the use of blunt skin hooks, safety scalpels, safety syringes, smoke evacuators, a separate ink supply during MMS, or 24-hour formalin fixation resulted in no exposures in 188 surveyed Mohs surgeons.¹⁸⁵ Postoperative measures that should be taken include the proper disposal of used sharps.

CONCLUSIONS

Dermatologists perform almost 10 million procedures annually; even in this context, the rate of surgical complications is very low, and the rate of serious surgical complications remains vanishingly rare. Adhering to standard safety recommendations may increase the level of safety for dermatologic surgeons and their patients, and developing protocols for management of surgical complications may help mitigate the severity of these problems when they arise. Critically, patients must be educated preoperatively regarding the risks associated with a given procedure, as managing patient expectations regarding the baseline risk of undesirable outcomes may help foster a team approach to care and management.

CHAPTER 37 Superficial Radiation Therapy and Electronic Brachytherapy

Mark S. Nestor
Jonathan Chan

SUMMARY

- Superficial radiation therapy (SRT) relies on low-energy photon radiation.

- SRT is a viable nonsurgical option for the treatment of select nonaggressive primary BCCs and SCCs in patients where surgical intervention is refused or inadvisable.
- An understanding of basic radiobiology is a prerequisite for utilizing any form of radiation therapy.

Beginner Tips

- The time–dose–fractionation (TDF) table provides a choice of protocols for a course of SRT based on the total dose of radiation, number of fractions, and duration of treatment.
- Hyperfractionated dosing regimens may yield an improved outcome.
- Ideally, radiation treatment for keloids should be administered within 2 days of surgical excision.

Expert Tips

- Various fractionation protocols may be used to accommodate the needs of each patient based on the size and location of the tumor, vascularity of the tissue, and the sensitivity of the tumor to radiation.

- Protocol modifications may include reducing the fraction size, increasing the number of fractions and total radiation dose, and changing the overall duration of treatment from the first fraction to the last.
- Modifying the size and number of the fractions and the total dose of administered radiation can prevent or minimize the occurrence of acute and latent radiation reactions while still optimizing the cure rate.

Don't Forget!

- While there is no immediate scarring from SRT, significant long-term scarring is possible, especially over time.
- Importantly, none of the recent SRT studies had a mean duration of follow-up greater than 5 years; therefore, long-term results should be viewed with caution.

Pitfalls and Cautions

- Acute reactions are defined as adverse events occurring within 90 days of administration of the first dose fraction.
- Latent reactions are defined as reactions occurring more than 90 days following the administration of the first fraction.

- Dyspigmentation and telangiectasias are seen frequently, and unlike surgical scars, which tend to improve over time, long-term sequelae of SRT tend to worsen over years and decades.

Patient Education Points

- While there is no surgical scar after SRT, it is *not* a scar-free procedure, and dyspigmentation, textural changes, and telangiectasias tend to increase over time.
- Therefore, this approach should be used with extreme caution in younger patients.

Billing Pearls

- Each SRT treatment should be billed using CPT code 77401. This code should only be used as a single unit, regardless of the number of areas treated per day.

CHAPTER 37 Superficial Radiation Therapy and Electronic Brachytherapy

INTRODUCTION

Superficial radiation therapy (SRT) uses low-energy photon radiation that minimizes penetration beyond the thickness of the skin.¹ Half of the energy is absorbed within the superficial layers of skin. On the electromagnetic spectrum, SRT waves are just above Grenz rays, low-energy or “ultrasoft” x-rays produced by 10 to 30 kV x-ray machines. Grenz rays have a half-value depth of 0.5 mm and are absorbed within the first 2 mm of skin tissue. Historically, there are numerous uses for SRT, though the primary use of the technology has been the treatment of nonmelanoma skin cancers (NMSCs) and the prevention of keloid scar recurrence.²

Among the numerous available methods for treating NMSC, SRT is an alternative treatment used by office-based dermatologists. In contrast with penetrating forms of radiation, such as electron beam radiation, SRT deposits 100% of its energy at the surface layer of the skin. With proper dosimetry and fractionation, it avoids deep tissue damage and causes minimal scarring. SRT results in acceptable cure rates for primary nonaggressive basal cell carcinoma (BCC) and squamous cell carcinoma (SCC) and a relatively low incidence of complications. It does not require that patients stop receiving

anticoagulants, and can be utilized safely in patients with poor circulation and contraindications for surgery. While the use of SRT steadily decreased during the past several decades, the recent availability of newer equipment and treatment strategies has led to a resurgence of SRT use for treating NMSC.

SRT is well suited for treating many anatomical areas.^{3–9} Most skin cancers occur on the scalp, forehead, eyelids, ears, nose, lips, cheek and chin, where surgical removal of large tumors may require reconstructive surgery.¹⁰ SRT may be beneficial for NMSC on the lower extremities, especially in elderly patients with background stasis dermatitis, chronic edema, or circulatory compromise.

There is no treatment-related discomfort associated with the use of SRT, making it ideal for patients that fear surgery or those with contraindications to surgical intervention.¹¹ Among patients with BCC, SRT improves quality of life despite the occasional occurrence of skin atrophy, dyspigmentation, alopecia, and telangiectasia.¹²

NONMELANOMA SKIN CANCER

In 2012, the National Cancer Institute estimated that 81,240 people (46,890 men and 34,350 women) would be diagnosed with BCCs and SCCs and that 12,190 people would die because of NMSCs.¹³ Based on the number of cases diagnosed in 2005 to 2009, the annual age-adjusted incidence of skin cancer is 23.0 per 100,000 men and women. The incidence among white patients is higher, with an incidence of 34.5 per 100,000 men and 21.3 per 100,000 women;¹³ however, the real incidence of skin cancer is considerably higher, as NMSC is excluded from most cancer registries. Based on a large US commercial insurance claims database, the actual incidence has been determined to be 693 per 100,000 persons or approximately 2,139,535 cases in the United States (0.7% of population).¹⁴ A study from South Florida estimated the annual incidence of NMSC to be 466.5 per 100,000 persons less than 65 years of age and 10,690 per 100,000 persons 65 years of age and older.¹⁵

Current evidence suggests that the incidence of skin cancer continues to increase from 1996 to 2008, the total number of skin cancer treatment

procedures increased by 53% from 1,480,645 to 2,152,615.¹⁶

Figures 37-1 through 37-4 demonstrate the use of SRT for the treatment of BCCs and SCCs in various patients. Figure 37-5 demonstrates the use of SRT for the treatment of an ear keloid.

Figure 37-1. Treatment of a nodular basal cell carcinoma of the nose with superficial radiation. This patient is a 73-year-old woman with a history of prior skin cancers and a biopsy-confirmed nodular basal cell on her right ala. After a discussion of the available treatment options, she elected to undergo treatment with SRT. The 5×6 mm lesion was circled with a 5-mm border and a 1.7-cm shield was fashioned out of 0.762-mm-thick lead and placed over the site in addition to intranasal and thyroid shielding. The patient received 500 cGy at 50 kV, 10 MA, the treatment time was .64 minutes with a TSD of 15 cm and zero filtration. The patient returned six more times over the next 3 weeks, receiving a total of 3500 cGy. The patient returned 14 days later and was pleased with the results. There was no recurrence after 4 years. Nodular basal cell carcinoma of the nose. (A) The 5×6 mm lesion was circled with a 5-mm border prior to treatment. Seven fractions of 500 cGy were delivered at 50 kV and 10 mA with a $D_{1/2}$ of 5.8 mm. (B) Posttreatment day 14. (C) There was no recurrence after 4 years.

Figure 37-2. Treatment of an in situ large squamous cell carcinoma of the eyelid with superficial radiation. The patient was a 93-year-old woman with a history of numerous difficult skin cancers on her face for which she had undergone multiple Mohs surgeries and skin grafts and flaps. She presented with a crusted lesion on her left lower eyelid. The lesion is near (medial) to a Mohs site repaired with a full-thickness skin graft for squamous cell carcinoma in situ 2 years earlier. This lesion was biopsied and found to be an actinic keratosis/squamous cell carcinoma in situ. Since the patient had undergone Mohs surgery of the left lower eyelid with full-thickness skin graft 2 years prior, Mohs surgery on this lesion could potentially worsen her existing slight ectropion. After discussing the use of Mohs surgery or SRT to treat this lesion, the patient chose SRT. The clinical lesion was identified and circled and a 5-mm border was drawn around this. A 0.762-mm-thick lead shield was custom made to include a 1.3-cm field and placed over the lesion and extended field. The patient was placed on the x-ray table in the supine position. One drop of tetracaine solution was instilled into her left eye and after 2 minutes, a lubricated gold-plated lead shield was placed inside the eyelid of the left eye. This was covered with the custom lead shield, while the right eye was covered with a standard lead eye shield and the thyroid was also covered with a lead shield. Using a 1.5-cm cone, seven fractions of 498.6 cGy (3490.2 cGy total) were delivered at 50 kV and 10 mA with a $D_{1/2}$ of 5.8 mm over a 3-week period which yields a TDF of 92. The patient tolerated SRT well and without complaints during the treatment regimen. She has no complaints of dry eye, or more than her usual amount of eye weeping. (A) The lesion was identified and circled, and a 5-mm border was drawn around this. (B) Two minutes after tetracaine solution was instilled into the left eye, a lubricated gold-plated lead shield was placed inside the eyelid of the left eye. (C) A custom 0.762-mm-thick lead shield was custom made to include a 1.3-cm field and placed over the lesion and extended field. (D) Using a 1.5-cm cone, seven fractions of 498.6 cGy (3490.2 cGy total) were delivered at 50 kV and 10 mA with a $D_{1/2}$ of 5.8 mm over a 3-week period which yields a TDF of 92. (E) Appearance of the eyelid 72 days posttreatment. (F) There was no recurrence after 15 months.

Figure 37-3. Treatment of an in situ squamous cell carcinoma of the upper lip with superficial radiation. This 83-year-old woman with a history of skin cancer was referred for the treatment of an actinic keratosis/squamous cell carcinoma in situ of the upper lip. Since she has a pacemaker and was being treated with warfarin, she wished to avoid surgery. The cancerous lesion was identified and circled and an additional 5- to 7-mm border was drawn around this. A 0.762-mm-thick lead shield was fashioned to include a 1.5×1.7 cm field and placed over the lesion and extended treatment field, and the eyes and thyroid were shielded. Using a 2.5-cm cone, nine fractions of 460 cGy (4140 cGy total) were delivered at 50 kV, 10 mA with a $D_{1/2}$ of 5.8 mm over a 3-week period. The patient tolerated the treatment well with only minimal erythema. The patient achieved a good cosmetic outcome at 2 months. (A) The cancerous lesion was identified and circled and an additional 5- to 7-mm border was drawn around this. (B) A 0.762-mm-thick lead shield was fashioned to include a 1.5×1.7 cm field and placed over the lesion and extended treatment field, and the eyes and thyroid were shielded. Using a 2.5-cm cone, nine fractions of 460 cGy (4140 cGy total) were delivered at 50 kV, 10 mA with a $D_{1/2}$ of 5.8 mm over a 3-week period. (C) The appearance of the lesion on the last day of treatment. (D) The patient achieved a good cosmetic outcome at 2 months.

Figure 37-4. Treatment of a squamous cell carcinoma of the left anterior lateral tibia. This 1.8×1.6 cm lesion was treated with SRT using a 1.0-cm margin. A 0.763-mm-thick lead shield was custom fashioned to a shield size of 3.2×3.2 cm. A 4.0-cm cone was initially selected to deliver 50 kV of 327.8 cGy at three fractionations per week with a treatment time of 0.44 minute per fractionation and a TDF of 99. The radiation prescription was changed after the seventh treatment (2294.6 total cGy delivered) in order to change to a larger 5.0-cm applicator. As a result, new values needed to be calculated for the total fractionation dose—three fractionations per week of 50 kV of 338.4 cGy for eight fractionations (2707.2 cGy total) with a treatment time of 0.45 minute per fractionation and a TDF of 99. The patient's total dose for this squamous cell carcinoma, located on the left anterior lateral tibia, totaled 5001.8 cGy over 23 fractionations. (A) Pretreatment. (B) 1 month postradiation. (C) 1-year postradiation.

Figure 37-5. Ear keloid treated with SRT of 6 Gy on postoperative days 1 to 3.

RADIATION PHYSICS

Radiation can be produced electronically, as in x-rays or electrons, or via the disintegration of unstable isotopes, as seen in alpha, beta, and gamma rays. Isotope therapy such as brachytherapy, or implantation techniques, may result in a less homogenous dose pattern. In dermatology, when treating with radiation, most lesions are treated by teletherapy—electronically produced radiation delivered at a distance from the radiation source. Photonic teletherapy is the radiation source for SRT.¹⁷

EQUIVALENT DOSE

A biologic-dose-equivalent number is useful, as the total dose of radiation is dependent on the manner it is administered. This biologic-dose-equivalent number compares different fractionation patterns. It was developed when patches of skin were exposed to different courses of radiation and the degree of short-term (acute) damage produced posttreatment was used to define

equivalent doses. From these experiments it was realized that as a treatment regimen lengthened in time, the larger the numerical total dose needed to be in order to produce an equivalent reaction.¹⁷

As demonstrated in the formula below, the nominal standard dose (NSD) can be related to the total numerical dose (D), number of fractions (N), and total time of a radiation course (T):

$$D = \text{NSD} \times N^{24} \times T^{11}$$

where D is the total numerical dose, N is the number of fractions, T is the total time (in days) of course of radiation.

Orton and Ellis published a set of derivative tables written in time–dose–fractionation (TDF) units in order to simplify this calculation. These tables enable physicians to properly select the equivalent acute responses based on daily dose, number of fractions per week, and total number of fractions.¹⁷

While there is not a clear understanding on how damage is produced radiobiologically, there are at least two components to damage: alpha (α) and beta (β). Some cells are killed after a single interaction (α killing). The number of cells terminated by α killing is directly proportional to the dose-per-fraction. While some cells are destroyed by a single interaction, other cells are only damaged, and these cells apparently have multiple targets that need to be destroyed for the radiation therapy to be completely lethal (β killing). This β killing of cells is proportional to the square of the dose-per-fraction.¹⁷

Clinically, there are many applications of α and β killings. Individual tissues each have an intrinsic property of α -to- β killing ratio. Tumors and rapidly dividing tissues have an α/β ratio of approximately 10. For more slowly growing tissues (i.e., normal connective tissue), the α/β ratio is approximately 3. Late complications are thought to occur in slowly proliferating normal tissues. As such, late complications are worsened by large doses per fraction. A commonly depicted form of the alpha–beta model states that for an equivalent amount of short-term damage, larger daily fractions will result in greater long-term damage:¹⁷

$$E = n(\alpha d + \beta d^2)$$

where E is the cell kill (measured in logs), n is the number of fractions, d is the dose of a single fraction of radiation (Gray units).

This occurs since cells involved in long-term damage are preferentially affected by β killing. Practically, this suggests that while different radiation regimens are equivalent in treating and controlling cutaneous carcinomas, the regimen that uses a higher dose-per-fraction (while reaching the same total dose) will ultimately lead to worse long-term cosmesis.¹⁷

DOSIMETRY—THE $D_{1/2}$ CONCEPT

The depth to which x-rays can penetrate tissue before being absorbed is directly proportional to their energy.¹ The half-depth-value depth ($D_{1/2}$) is defined as the depth of tissue required to absorb or attenuate the x-ray beam by 50%. By knowing the desired $D_{1/2}$, the appropriate x-ray energy can be chosen to achieve the desired clinical effect while minimizing exposure to healthy underlying tissue. For skin cancers, the selected $D_{1/2}$ should be greater than the maximum measured depth of the tumor.¹

The quality of the radiation can also be improved by the use of filtering materials such as aluminum. When placed in the x-ray beam, filters absorb low-energy rays and increase the homogeneity and mean energy of those x-rays reaching the tumor while also increasing tissue penetration.¹ The total treatment time will increase, however, because filtration reduces the overall radiation intensity.

FRACTIONATION THEORY

Ionizing radiation damages both cancerous and normal cells; however, healthy cells exposed to sublethal doses of radiation are better able to repair themselves and survive than cancer cells. Therefore, administering the total dose of radiation in smaller fractions over longer periods will have maximal harmful effects on cancer cells but minimal effects on healthy cells. Thus, fractionation improves the therapeutic index of radiation therapy.

Various fractionation protocols may be used to accommodate the needs of each patient based on the size and location of the tumor, vascularity of the

tissue, and the sensitivity of the tumor to radiation.¹ Protocol modifications may include reducing the fraction size, increasing the number of fractions and total radiation dose, and changing the overall duration of treatment from the first fraction to the last. Modifying the size and number of the fractions and the total dose of administered radiation can prevent or minimize the occurrence of acute and latent radiation reactions while still optimizing the cure rate.

Acute reactions are defined as adverse events occurring within 90 days of administration of the first dose fraction. These reactions typically occur in areas of rapidly dividing normal cells within the treatment zone when doses of radiation are administered too frequently, and there is insufficient time for healthy cells to repair themselves. Common acute reactions include pain, erythema, and moist desquamation. Radiation doses exceeding 500 cGy per fraction in areas of low vascularity may lead to cell death and ulceration.

Latent reactions are defined as reactions occurring more than 90 days following the administration of the first fraction. These reactions can be controlled by monitoring the dose-per-fraction and the overall total radiation dose. Common latent reactions include skin atrophy, telangiectasias, and hypo- or hyperpigmentation. One of the most important innovations in radiation therapy is an improved understanding of the role of fractionation in improving outcomes and minimizing acute and latent effects.

FRACTIONATION TABLES

The TDF table provides a choice of protocols for a course of SRT based on the total dose of radiation, number of fractions, and duration of treatment (Table 37-1). This table is based on the work of early investigators who established clinical relationships between the radiation dose and fractionation to cancer cure and adverse effects.^{18,19} The TDF table provides the number of treatment fractions on the x-axis and the radiation dose for each fraction on the y-axis. It is generally assumed that treatments will be administered three to five times weekly; therefore, it will take 5 to 8 weeks to administer 24 fractions.

Table 37-1. Time–Dose Fractionation Factors^a

and neck lesions. Commonly used fractionation schedules used for treating skin cancers are shown in [Table 37-2](#).

Table 37-2. Common Fractionation Protocols Used for Treating Skin Cancers

TDF Number	Radiation Dose/Fraction (cGy)	Fractions/Week	Total Fractions	Total Radiation Dose (cGy)
98	380	3	12	4560
100	380	2	13	4940
100	320	3	16	5120

TREATMENT INTERRUPTIONS

A full course of SRT typically requires several weeks, and treatment may be interrupted for various reasons before completion. In these cases, a Decay table should be consulted when treatment resumes ([Table 37-3](#)). The number of completed treatment days is indicated on the y-axis and the length of the rest or interruption is indicated on the x-axis. These values correspond with the adjusted TDF number that should be used for the remaining duration of therapy.

Table 37-3. Decay Factors for Disrupted or Split-Course Radiotherapy

Treated Days (T)	Rest Period (R)											
	5	10	15	20	25	30	35	40	50	60	80	100
5	0.93	0.89	0.86	0.84	0.82	0.81	0.80	0.79	0.77	0.75	0.73	0.72
10	0.96	0.93	0.90	0.89	0.87	0.86	0.85	0.84	0.82	0.81	0.79	0.77

Note: Treated days are the number of completed treatment days prior to disruption. Rest period (days) was the duration of treatment disruption. The corresponding numbers are the decay factor, or adjusted TDF when treatment resumes.

FIELD SIZE

Due to the inability to histologically examine the margins of an irradiated tumor, treated tissue margins should be slightly larger than those required for a surgical excision. For a typical, well-demarcated lesion, margins of 1 cm

are sufficient. Large tumors and tumors with less well-defined borders may necessitate margins up to 2 cm.¹⁷ The use of customized lead shields limits radiation exposure to only the cancerous lesion and healthy tissue immediately surrounding it (Fig. 37-6).

Figure 37-6. Custom lead shielding—using the tools shown, lead shields can be quickly fabricated to suit the needs of any patient undergoing SRT.

ALTERNATIVE RADIATION THERAPY MODALITIES FOR NMSC

Electron Beam Therapy

An alternative to SRT is electron beam therapy (EBT) whose energy source, an electron, is a charged particle; as such, EBT requires a linear accelerator. EBT is the treatment of choice by radiation oncologists to treat NMSC. EBT can be used to treat broader areas as well as deeper tumors in complex topographic treatment sites.²⁰ In the treatment of cutaneous malignancies with

EBT, radiation oncologists apply a bolus, a tissue-equivalent material, to the skin in order to shift the efficacious portion of the electron beam toward the skin surface.²¹

Superficial Radiation Therapy versus Electron Beam

In a review of cases treated at Mallinckrodt Institute of Radiology in St. Louis of 339 patients, cure rates of head and neck NMSC were slightly better when treated with SRT than EBT. This was felt to be due to a higher chance of underdosing EBT than SRT. For BCC with a size <1 cm, SRT had a cure rate of 97% (69/71) compared to EBT cure rate of 92% (11/12). For SCC with a size <1 cm, SRT and EBT cure rates were 100% (12/12) and 75% (3/4), respectively. In BCC measuring 1 to 1.5 cm, SRT cure rate was 93% (84/90) versus EBT cure rate of 73% (16/22). In SCC measuring 1 to 1.5 cm, SRT and EBT cure rates were 91% (10/11) and 70% (7/10), respectively. For larger BCC with a size >5 cm, SRT had a cure rate of 100% (4/4), while EBT cure rate was 92% (11/12). In SCC with a size >5 cm, SRT and EBT cure rates were 100% (1/1) and 75% (3/4), respectively.²² Still, there is an established role for EBT as adjunctive therapy in tumors with perineural invasion, treatment of cutaneous T-cell lymphoma (CTCL), Merkel cell carcinoma, dermatofibrosarcoma protuberans (DFSP), scalp tumors, and select melanomas of the head and neck.²⁰

High-Dose Rate Brachytherapy

High-dose rate (HDR) brachytherapy, an isotope therapy, involves the placement of radioactive sources directly onto or into target tissues.¹⁷ Several disadvantages limit the use of HDR brachytherapy, including a lower cure rate in NMSC that exceed a depth of 2 mm and a diameter greater than 2 cm. Even in ideal candidates, recurrence rates range from 0% to 10%. HDR brachytherapy also poses logistical challenges, as expensive hardware is required including applicators and sophisticated HDR after loading equipment. Additionally, there are potential risks of radiation exposure to medical personnel.²³

Electronic Brachytherapy

Electronic brachytherapy (E-brachytherapy) differs from HDR brachytherapy as it delivers surface brachytherapy without radioactive isotopes or linear accelerators. It is essentially SRT with the radiation source present closer to the skin. As a result, the need from extensive shielding, as required with HDR brachytherapy, is eliminated.²⁴ It also limits the size of the applicators to approximately 50 mm versus 180 mm for SRT. In a clinical study involving 122 patients with 171 NMSC lesions, E-brachytherapy was administered at 40 Gy in 8 fractions and delivered twice weekly. These patients were followed up to 1 year with good cosmetic results—no marked atrophy, gross telangiectasias, severe induration, loss of subcutaneous tissue, ulceration, or necrosis.²⁵

Two prospective, single-center, nonrandomized, pilot studies treated 40 patients (20 patients in each study) with E-brachytherapy for superficial and nodular BCCs. Group 1 patients received 36.6 Gy in 6 fractions of 6.1 Gy resulting in a 90% response at year 1 and Group 2 patients received 42 Gy in 6 fractions of 7 Gy resulting in a 95% response at year 1; both groups exhibited acceptable cosmesis.²⁶

Summarized data presented in abstract format at national meetings demonstrated a recurrence rate of less than 1% with E-brachytherapy. Most lesions were BCCs (57%) or SCCs (38%) less than 2 cm in size (97%). These NMSC lesions were treated with 40 to 45 Gy using mostly 8 fractions. Good cosmetic results accompany the recurrence rate of less than 1%, but these results are limited by a median follow-up of only 4 to 16 months.²⁷ Thus further study is needed to better quantify both response and recurrence rates.

CLINICAL EFFICACY OF SRT FOR NONMELANOMA SKIN CANCERS

Several retrospective studies have evaluated the safety and efficacy of SRT for the treatment of more than 3000 BCCs and SCCs.^{3,5,28,29} One retrospective analysis was performed on 1715 histologically confirmed primary cutaneous BCC and SCC treated with superficial x-ray therapy at a

single site over a 10-year period (2000–2010).³ These included 712 histologically proven BCC (631 nodular and 81 superficial), 994 SCC (861 in situ and 133 invasive), and 9 with distinct features of both BCC and SCC in the same biopsy specimen. Kaplan–Meier estimates (95% CI) of cumulative rates of tumor recurrence at 2 and 5 years were 1.9% (1–2.7%) and 5.0% (3.2–6.7%), respectively. The recurrence rate for BCC at 2 and 5 years was 2% (0.8–3.3%) and 4.2% (1.9–6.4%), respectively, and 1.8% (0.8–2.8%) and 5.8% (2.9–8.7%) for SCC, respectively. Tumors on male patients >2 cm in diameter were associated with a significantly increased likelihood of recurrence. This study, the largest to date, represented the experience of a single dermatology office. Others have reported 5-year cure rates for BCC and SCC to be 94.4% and 92.7%, respectively, following SRT and 15-year cure rates to be 84.8% and 78.6%, respectively.²⁸ Tumor control was 98% for lesions <1 cm, 93% for lesions 1 to 5 cm and 100% for lesions >5 cm.⁵

A retrospective review of 233 BCCs, some of which were recurrent, treated with radiotherapy with different fractions and levels of radiation was also performed. These BCCs were mostly on the face and scalp, with a few located on the trunk and extremities. Multiple fractions were used (an average of 10) and radiation levels ranged from <40 to >60 Gy, dependent on the size of the lesion. With a median follow-up time of 5.8 years, cure rates in previously untreated lesions was 94% and in recurrent lesions was 90%. A cosmetic rating of good or excellent was achieved in 92% of lesions. A long-term side effect of soft tissue necrosis was experienced in 2%, while cartilaginous necrosis was seen in one lesion, and bone necrosis occurred in two lesions. Local tumor control, cosmetic result, and complications were related to the maximal diameter of the lesion and the pathologic tumor type. Treatment type, patient age, and duration of treatment were not found to be associated with response.³⁰

Another review of 1267 NMSC lesions (1019 BCC, 245 SCC, and 3 mixed types) were irradiated with energies from 45 to 60 Gy with 8 to 10 fractions. Five-year cure rates for BCC and SCC were 94.8% and 90.4%, respectively. 2.4% of all tumors recurred at the irradiated border, and recurrence was related to tumor size, thickness, and TDF number. Side effects included hypopigmentation (72.7%), telangiectasias (51.5%), erythema (44.5%), and hyperpigmentation (23.4%).³¹

A meta-analysis of 14 retrospective studies pooled 1018 primary SCC lesions treated with radiotherapy of various energies and fractions. With a mean duration of follow-up between 2 and 5 years, the average local cure rate was 93.6%, while age and tumor size were correlated with risk of local recurrence (6.4%). Importantly, none of the studies had a mean duration of follow-up greater than 5 years.³²

Radiation Therapy Side Effects

Radiation dermatitis, with associated erythema, vesiculation, and ulceration, is a known side effect of SRT.³³ Acute reactions, such as erythema and mild discomfort, are to be expected and can be treated with mild emollients. Expected healing time of acute reactions is approximately 4 weeks after cessation of radiation therapy. Late reactions occur months to years later and can include hyperpigmentation, hypopigmentation, telangiectasias, and skin atrophy. These late reactions can be irreversible or may require more extensive treatment; for example, radiation-induced ulcers may benefit from debridement, skin grafts, antibiotic therapy, and other interventions.³⁴ Dyspigmentation and telangiectasias are seen frequently, and unlike surgical scars, which tend to improve over time, long-term sequelae of SRT tend to worsen over years and decades. Therefore, this approach should be used with extreme caution in younger patients.

Radiation Therapy Caveats

The proper and judicious use of superficial photon RT is critical; while there is a long tradition of dermatologists using radiation, it should always be utilized in the appropriate setting and for the appropriate patient.³⁵ Treatment failures with radiation can and do occur, though they may be minimized by careful selection of lesions and a thorough understanding of tumor subtype, depth, and clinical extension. Based on these factors, an appropriate depth dose, field size, and radiation plan and dosimetry will help secure a good chance of cure; however, other factors are needed to assure that the prescribed dose is delivered with minimal to no deviation during the course of fractionation. To reliably deliver the dose to the tumor bed, proper patient positioning, immobilization, and shielding can be repeatedly tested and fine-

tuned during simulation. Any variance in shield position or RT cone contact can result in the undertreatment of a tumor.

Old vs. New Radiation Devices

Newer machines have built-in safety features such as automated filtration placement, daily internal rad check, calibration, and desired and cumulative dose display during treatment. Many older machines accept added filtration to harden the beam for deeper tumors and require extra precautions, since failure to place the filter will lead to overtreatment, while failure to remove the filter for other calibrated depth dosages will lead to undertreatment.

Other concerns with older units include the need to be warmed up prior to treatment, and lack solid-state design necessitating careful monitoring and adjustment of the voltage and current during treatment. Older machines may allow the use of various cones with different target skin distances which require strict attention to calibration tables to avoid under- or overdosing. This is because photon RT output is inversely dependent on the square of the distance from the energy source. The calculation of dose in both older and newer machines should include a redundant hand calculation of the dosage using calibration tables specific to each machine at each different voltage settings, cone sizes and target skin distances.³⁶ Thus, with proper attention to detail and safety checks, both older and newer devices are reasonable options for the delivery of SRT.

USE OF RADIATION THERAPY FOR RECURRENT KELOIDS

In addition to being utilized for the treatment of NMSC, SRT can be utilized for treating recurrent keloids. Hypertrophic and keloid scars are common, and in addition to being cosmetically bothersome, may be symptomatic as well. Traditional treatments include topicals, intralesional 5-fluorouracil (5-FU), and intralesional steroids. Surgical excision has been used as well, but is similarly associated with a not insignificant recurrence rate. In a literature review of studies from 1942 to 2004 regarding the treatment of keloids with

either scalpel or laser excision, the weighted average recurrence rate was 71.2%.^{37,38}

Keloid recurrences can be significantly reduced with postoperative SRT. In a retrospective study of 80 keloidectomy patients treated postoperatively with a single fraction of 10 Gy radiotherapy, a 1-year relapse rate of 9% and a 5-year relapse rate of 16% were seen.³⁹

Another retrospective study of 76 ear keloids, the 5-year relapse-free rate was 79.8%. These keloids were treated postexcision with 5 Gy/week (a total dose of 25–45 Gy) of contact or superficial radiotherapy 1 to 3 days postoperatively. The mean follow-up was 47.85 months, and there were no adverse events of pigmentation or telangiectasias.⁴⁰

Ideally, radiation treatment for keloids should be administered within 2 days of surgical excision. A biologically effective dose (BED) value of 30 Gy can be obtained through multiple methods: a single acute dose of 13 Gy, 2 fractions of 8 Gy, 3 fractions of 6 Gy, or a single dose of 27 Gy at a low-dose rate. This radiotherapy regimen is recommended to keep keloid recurrence rates less than 10%.²

Most protocols implementing SRT postsurgical excision of keloids involve healing by primary intention, but a small study investigating radiation therapy for the prevention of keloids after shave excision resulted in no recurrence at a 5-month follow-up. With the shave excision, wounds were allowed to heal by secondary intention for 69 days. This time period was followed by three radiation treatments.⁴¹

EBT can also be selected for treatment after keloidectomy. One study examined the treatment of 91 keloids with combination surgical excision and postoperative electron beam radiation. 20 Gy were delivered at 5 fractions, but the protocol was modified for keloids on the ear to 16 Gy at 4 fractions. This study demonstrated a recurrence rate of 44%, though the presence of symptoms was considered a recurrence.⁴²

CONCLUSIONS

There has been a recent increase in the use of SRT for treating nonaggressive BCC and SCC. This resurgence is due in part to the availability of new

equipment, though reimbursement trends may be responsible for some of this increased interest as well.

SRT is a viable nonsurgical option for the treatment of select nonaggressive primary BCCs and SCCs in patients where surgical intervention is refused or inadvisable. While not a first-line treatment for most NMSCs, SRT is well suited for use by dermatologists in the office setting.

CHAPTER 38 Reconstruction of the Eyelids

Andrea Willey
Richard Caesar

SUMMARY

- Eyelid reconstruction lies at the crossroads of multiple surgical specialties, and presents distinct challenges for the periocular surgeon.
- The unique multilaminar composition of the eyelids, freely mobile yet bound by fixed bipolar attachments, is vulnerable to tensional forces that require diligent management to preserve their unique anatomic and functional relationships.

Beginner Pearls

- Preoperative evaluation and collaboration with ophthalmic and oculoplastic specialists when indicated is essential for optimal outcomes.
- Knowledge of and familiarity with the management of tension are essential to periocular surgery.
- Tension on the lid margin should be assessed pre-, post-, and intraoperatively to ensure the lid remains in optimal position snug against the globe.

Expert Pearls

- Keeping tension parallel to the lid margin is the cornerstone of periocular repairs, and is often balanced with placing incisions along relaxed skin tension lines.
- Transposition flaps and rotation flaps are useful for many periocular defects.
- Primary repair of full-thickness lid defects is fundamental to more advanced reconstructive techniques.

Don't Forget!

- Reconstruction of larger full-thickness lid defects involves a progressive approach with a combination of techniques to repair the anterior and posterior lamella.
- Suspension sutures should be used routinely to support periocular repairs and avoid ectropion, even when the canthal support has not been disrupted by tumor extirpation.

Pitfalls and Cautions

- Full-thickness skin grafts must be appropriately sized with the defect on full stretch to avoid excessive wound contraction and ectropion.
- Complications include bleeding, infection, hematoma, chemosis, epiphora, dry eye, suture granuloma, trichiasis, lid notching, scleral show, asymmetry, ectropion, and webbing.
- Even mild ectropion can cause significant epiphora and discomfort and may require a slit-lamp examination to evaluate for corneal abrasion.

Patient Education Points

- Select patients undergoing extensive surgery around the eye may have a preoperative ocular examination and consultation with an oculoplastic surgeon to ensure a smooth transition of care if needed.
- Both ectropion and webbing tend to occur 2 to 4 weeks postoperatively during maximal wound contraction. Correction usually requires flap revision and canthopexy procedures.

Billing Pearls

- Excisions and repairs on the eyelid rely on the standard code series; keep in mind that placement of suspension sutures in a linear repair is likely sufficient to elevate a layered closure to complex status.

CHAPTER 38 Reconstruction of the Eyelids

INTRODUCTION

Eyelid reconstruction lies at the crossroads of multiple surgical specialties, and presents distinct challenges for the periocular surgeon. The unique multilaminar composition of the eyelids, freely mobile yet bound by fixed bipolar attachments, is vulnerable to tensional forces that require diligent management to preserve their unique anatomic and functional relationships. The eyelids not only protect the globe and provide a tear film necessary for visual perception, but also hold great aesthetic significance. An understanding of anatomy, principles, and fundamental techniques of periocular surgery is a prerequisite for addressing methods of managing tension on the eyelids.

PREOPERATIVE ASSESSMENT AND MANAGEMENT

A thorough ocular history and examination assessing visual acuity, intraocular pressure, and tear film/dryness may be recommended before surgery. A preoperative consultation with an oculoplastic surgeon is prudent for patients who are likely to need multispecialty collaboration, or patients with significant pre-existing eye disease. In addition, conditions of dry eyes or xerophthalmia should be diligently managed in the perioperative period. For recurrent tumors or tumors with suspected extension into the orbit or medial canthal structures, imaging with CT or MRI may be indicated. Taking clinical photographs before and after surgery is prudent for all patients.

Instrumentation and preparation

Bishop Harmon forceps

Wescott spring scissors

Stevens tenotomy scissors

Castroviejo needle holders

Desmarres retractor

Jaeger lid plate

Bowman lacrimal probe

Cox II metal shields

Fine tissue hooks

Calipers

Bipolar unit or hot loop cautery

5-0, 6-0, 7-0 polyglactin sutures spatulated needles

6-0 polypropylene sutures

Proparacaine hydrochloride ophthalmic drops

2% lidocaine hydrochloride with epinephrine

Erythromycin ophthalmic ointment

Nonstick eye pads

Metal or plastic eye shield

Assessment and control of potential bleeding is necessary to prevent complications during periocular surgery. Management or cessation of anticoagulants is indicated for large tumor extirpations or repairs that breach the orbital septum to minimize the risk of retrobulbar hemorrhage. Control of blood pressure in hypertensive patients is also important to minimize risks of

bleeding. Meticulous intraoperative control of bleeding and postoperative observation and counseling is essential. In addition, anxiolytic medications with appropriate monitoring can be useful during periocular surgery.

The periocular skin is cleansed with povidone–iodine or hypochlorous acid antiseptic.¹ Chlorhexidine solution is contraindicated as a periocular prep agent, as it may lead to complications including keratitis, corneal opacification, and ulceration.² Local anesthetic with epinephrine is infiltrated subcutaneously, and transconjunctivally, as this is usually less painful for repairs involving the eyelid itself. Adequate time must be allowed for the vasoconstrictive effects of epinephrine to take effect. Topical anesthetic ophthalmic drops are applied prior to placement of a corneal shield.

Plastic or metal corneal shields can be useful to protect the globe from trauma and light during surgery, but are not mandatory if care is taken while working around the eye. Corneal shields must have a smooth surface and fit properly. Care should be taken so that caustic substances do not get under the shield, which can damage the cornea.

ANATOMY

A comprehensive understanding of the distinct anatomic features of the eyelids is necessary for repairing surgical defects of the eyelids and periocular skin.³ The eyelids are a multilaminar structure comprising conjunctiva, tarsus, muscle, and skin, with various incorporated glands and appendages. The eyelids are suspended firmly to the bony orbit by tendons at the lateral and medial canthi and loosely surrounding soft tissue layers. Eyelids protect the globe and harbor glands that create the outer oil layer of the tear film required for clear vision. The relationships and attachments between the eyelid and surrounding soft tissue are essential for eyelid mobility and are the crux of expression and beauty.

The upper lid tarsus is curved in the shape of the globe where it rests smoothly along the surface with the medial puncti exposed to the lacrimal lake on blinking. The skin of the eyelid is thin, adherent over the tarsus of the palpebral lid. The posterior edge of the lid margin is sharper than the more rounded anterior edge with emanating lashes. This anatomic feature is a useful landmark for primary lid closures. The tarsus provides the structural

support of the lid. The tarsus also houses the meibomian glands, which secrete the oily portion of the tear film that keeps tears from evaporating.

Conceptually, the lid is divided into anterior and posterior lamella, defining a plane of surgical division, which may be reconstructed independently. The posterior lamella is comprised of the conjunctiva and tarsus, the structure of the lid, and its mucosal lining, while the anterior lamella is comprised of the skin and orbicularis muscle. The orbicularis muscle consists of the orbital portion, which acts like a sphincter by forming an ellipse within the orbit and converging at the medial raphe of the canthus, and the tarsal and septal palpebral portions, which overlie the upper and lower tarsi, respectively.

The palpebral orbicularis oculi muscles become contiguous with canthal tendons laterally before attaching to Whitnall's tubercle, a bony prominence inside of the bony orbit, 4 mm posterior to the orbital rim just superior to the canthal apex. Whitnall's tubercle is also the site of convergence of Whitnall's and Lockwood's ligaments, the pulley system of the lid motion and the supportive tissues of the lateral retinaculum. Medially the orbicularis muscle forms the complex structure of the lacrimal pump, dividing into superficial and deep heads around the lacrimal canaliculi before attaching to the bony orbit at the maxilla and anterior and posterior lacrimal crests housing the lacrimal sac.

The vascular supply of the upper and lower eyelids supplied by the internal and external carotid arteries is comprehensive and generous, allowing for ready healing of surgical wounds ([Fig. 38-1](#)). Inferiorly the facial artery joins the dorsal nasal artery at the medial canthus just medial to the attachment of the canthal tendon to supply the upper and lower lids. The superficial temporal, lacrimal, and transverse facial arteries anastomose to form upper and lower palpebral arcades.

Figure 38-1. Periocular vascular anatomy.

The muscular innervation of the orbicularis is supplied by numerous branches of the facial nerve, which are responsible for both the constitutive tone as well as the active sphincter-like motion of the orbicularis. When muscular innervation is compromised, osteocutaneous suspension sutures are useful to maintain the position of the eye and prevent ectropion. Sensory innervation of the orbicularis is supplied by numerous branches of the trigeminal nerve. Sensory and sympathetic motor nerves of the globe originate from the ciliary ganglion.

PERIOCCULAR TENSION MANAGEMENT

An intimate understanding of tension capacity of the eyelids relative to surrounding structures, and the varying degrees of laxity that come with age, is essential to avoid complications of ectropion and webbing. Highly sensitive tensional forces on the eyelid are created by the combined effects of thin and mobile skin of the eyelids and soft tissue, which are fixed to the

bony orbit bilaterally and surrounded by thicker skin bound to the underlying retinaculum.

These unique relationships allow for the mobility of the eye and are necessary for the lids to open and close and for concentric movement of the orbicularis. However, this mobility of skin and soft tissue also reacts readily to external forces, including gravity and wound contraction. As the bony structures of the orbit change with age, the soft tissue and tendinous attachments loosen, creating a lower threshold for tensional forces to pull the lid away from the globe and can disrupt the function of the lids and lacrimal puncti. Similarly, the thin and mobile skin of the medial canthus, tethered by more firmly attached surrounding skin that facilitates the vertical movement of facial expression, moves readily to create a web. Knowledge and appreciation of these tensional forces is invaluable in maintaining function of the eye and avoiding the pitfalls of ectropion and webbing.

Preoperative assessment of the degree of laxity of the lower lid is typically done by assessing how far the lid distracts downward when gently pulled or how rapidly the lid snaps back when pulled away from the globe. Easy distraction or slow recoil indicates a lower threshold for vertical tension during lid repair and wound contraction. An appreciation for the degree of normal tension can be gained with experience. The degree of lid tension is assessed intraoperatively and postoperatively by having the patient simultaneously gaze upward and open the mouth widely. If the lid pulls away from the globe during this maximal vertical tension, additional support is needed, usually in the form of flap adjustment, suspension sutures, and/or canthopexy.

CANTHOPEXY AND SUSPENSION SUTURES

Numerous canthopexy procedures have been described for effective support of the lid margin and canthi during periocular surgery.⁴⁻⁶ Suspension sutures can be placed in periosteum along the orbital bone or through retinaculum and fascial layers to support flaps and grafts and actively minimize tension on the lid margin.⁷⁻¹¹ A simple lateral canthopexy can be performed through an existing defect or by making a linear skin incision a few millimeters lateral to the lateral canthus followed by blunt dissection to the orbital rim. A metal shield is used to protect the globe as a 5-0 polyglactin suture on a

spatulated needle is passed through the tarsus and then through the periosteum at a shallow angle (from inside to outside) along the inner orbital rim at Whitnall's tubercle. The suture is then carefully secured using graduated tension until the tarsus is delicately secured to the orbital rim without over tightening. Medially, flaps can be suspended to the periosteum medial to the insertion of the medial canthal tendon, or to the tendon itself.^{12–14} Care must be taken not to pass the suture into the underlying lacrimal structures.

RECONSTRUCTION OF ANTERIOR LAMELLAR DEFECTS

There are many options for reconstructing defects involving the periocular skin and eyelids, depending on the location, size and depth of the defect, the surrounding skin reservoirs, and laxity of the eyelids. The aim of periocular reconstruction is to repair the defect while maintaining the position of the eyelid, punctum, and canaliculi, avoiding vertical tension on the eyelid during surgery, and actively preventing any imbalance of tension associated with wound contraction during the perioperative period.

Linear Repairs

Linear repairs of wounds around the eye require a balance of keeping incisions perpendicular to the lid margin and obscuring incisions in relaxed skin tension lines (RSTL). Vertical incisions below the lid margin can be made in an increasingly oblique manner around the lower eyelid, except in the medial canthus where horizontal incisions are strictly avoided to prevent webbing (Fig. 38-2). Deep sutures can help to guide tension horizontally to allow for more oblique skin incisions. M-plasty repairs or simply leaving redundant cones can be useful for defects close to the lid margin. Small defects located on the upper lid crease can often be repaired with a traditional crescent-shaped blepharoplasty incision along the natural crease, keeping incisions lateral to the caruncle to avoid webbing and extending beyond the lateral canthus when hooding is present. Due to the mobility of skin inside the bony orbit relative to the surrounding thicker bound periorbital skin, even defects outside the orbit that are repaired with incisions directed perpendicular to the lid margin can result in ectropion

during wound contraction if the lid is sufficiently lax. Evaluating tension on the lid intraoperatively can help identify excessive tension. Periosteal suspension sutures can be placed around the eye when needed to support the lid during the perioperative period.⁷⁻¹¹

Figure 38-2. Linear repairs balance incision lines perpendicular to the lid margin and within relaxed skin tension lines. Vertical incisions can be made in an increasingly oblique manner around the lower lid, except in the medial canthus where horizontal incisions are strictly avoided to prevent webbing. Incisions on the upper lid can be made within the natural lid crease.

Skin Grafts

Full-thickness skin grafts are commonly used for anterior lamellar defects of the upper and lower lids and medial canthus when direct closures are not possible. Adequate sizing of grafts is imperative to avoid ectropion

associated with wound contraction. In general, grafts should be 25% to 30% larger than the defect when placed inside the bony orbit.¹⁵ More precise sizing for defects below the lid margin can be determined by placing the lower lid on full stretch upward with forceps or a suture to expand the defect maximally. A sterile nonadherent gauze pad can be used as a blotter to create a template with the lid on full stretch.^{16,17} Ipsilateral and contralateral upper eyelid crease provides the ideal tissue match and is well vascularized for rapid inosculation. Other donor sites include pre- and postauricular skin, supraclavicular, and inner arm skin. Grafts from these areas must be thinned significantly to improve tissue match and reduce bulkiness. Grafts can be fenestrated and tacked to the wound bed if needed. Dental wax or vaseline gauze bolsters can be used for gentle pressure postoperatively. Canthopexy sutures can be placed to support the lower lid and avoid ectropion associated with wound contraction. Modified Frost sutures can be placed to support the lid during the immediate postoperative period while tissue swelling may lead to tension on the lid margin.¹⁸ Split-thickness grafts are generally avoided in this area due to the possibility of excessive wound contraction.

Flaps

Numerous flaps have been used to successfully reconstruct the periocular area.^{19,20} While the characteristics of the defect and the surrounding tissue will determine the appropriate repair, a regional approach to periocular repairs according to surgical zones can be useful (Figs. 38-3 and 38-4).^{13,21–23} Regardless of choice of repair, it is imperative to design and support flaps and grafts in the perioperative period to minimize forces of gravity, edema, and wound contraction that may distract the lid away from the globe, causing complications of lid malposition, corneal exposure, lacrimal dysfunction, or suboptimal cosmesis. Ancillary suspension sutures, including medial and lateral canthopexy procedures, are used routinely during periocular repairs to prevent ectropion, especially in elderly patients with significant laxity, even if the eyelid or canthal support system is not disrupted by tumor extirpation.^{21,13} The following is a regional approach to periocular reconstruction and canthal support procedures that reliably repairs anterior lamellar and full-thickness lid defects.

Figure 38-3. Modified zones of periocular reconstruction. Reconstructive options in the periocular region can be classified by surgical zone. 1. Upper lid. 2. Lower lid. 3. Medial canthus. 4. Lateral canthus. 5. Periorbital cheek. Reconstructive options for zones 2 and 4 are similar.

Figure 38-4. Regional approach to periocular flap repairs.

LOWER LID AND LATERAL CANTHI

Designing flaps with tension vectors parallel to the lid margin is a cornerstone of periocular reconstruction, particularly below the lid margin and at the lateral canthus where the lid is most vulnerable to distraction. Rhomboid transposition flaps that “push tissue” toward the lid margin, redirecting tension vertically and efficiently repairing wounds with minimal undermining beyond the flap, are workhorse flaps for small and medium defects below the lid margin and outside the canthi (Fig. 38-5). When adequately sized to minimize tension, scars are minimally visible despite crossing cosmetic unit borders. The size of the rhomboid flap must be large enough to account for pivotal restraint and secondary movement of the wound

edge, wound contraction, upward gaze, and maximal tension, as well as to avoid complications of ectropion. Transposition flaps based on the infraorbital cheek skin are useful for central defects below the lid, including those very close to the lid margin, as they soundly direct tension superiorly (Fig. 38-6). More lateral defects below the lid margin can be repaired with transposition flaps that use the redundant skin of the upper lid crease (Fig. 38-7).^{24,25} Canthal suspension sutures provide additional support when indicated. Laterally based rotation flaps are useful for defects exceeding the limits of the upper lid reservoir (Fig. 38-8).

(B) Periosteal suspension suture is placed to support the cheek below the flap and relieve tension on the lid margin. (C) Lid margin snug against the globe with max tension postoperatively. (D) Tension-free flap 6 months postoperatively.

Figure 38-8. Temple rotation flap. (A) Defect exceeding reservoir on the upper lid crease. (B) Arc of rotation extending above the lateral canthus and incisions placed in RSTL. (C) Tension-free flap 2 months postoperatively with incision lines obscured in rhytids.

Larger defects below the lid margin are reliably closed with rotation flaps that take advantage of the ample cheek reservoir and partially obscure incisions in the subciliary and hair lines (Fig. 38-9).²⁶ Rotation flaps can lengthen the circumference of flaps and redistribute tension vertically beyond the canthi,²⁷ and thus are often preferred to straight advancement flaps, except for small vertically oriented defects that can be repaired with minimal tension. Ideally, incisions along the subciliary skin extend above and lateral to the outer canthus before curving downward along the hairline. This way, vertical tension originates lateral to the lid margin and incision lines can be

partially obscured in RSTL. Pivotal restraint can be reduced by placing a back cut in the hairline or behind the ear, but this is often not necessary.

Figure 38-9. Cheek rotation flap. (A) Large medial defect extending above and below the lid margin. (B) Flap undermined with the arc of rotation at the lateral canthus, incisions in RSTL, and ample tissue in the medial canthus. (C) Lid snug against the globe with maximal tension postoperatively. (D) Tension-free flap 5 months postoperatively.

Advancement flaps that slide tissue horizontally are effective for a variety of defects below the lid. Obscuring a portion of the scar in the subciliary border while displacing the dog ear beyond the canthi is advantageous, though undermining can be considerable for larger defects, and requires greater care within the orbital septum where retinaculum and adipose tissue are minimal. Dog ears can be repositioned, though tension vectors for advancement flaps are not redirected and wound contraction can still occur

in a vertical direction. Small vertical defects where redundant cones can be left standing are easily closed with purely horizontal advancement flaps.

Inferiorly based advancement flaps that easily mobilize the malar skin are useful for medial defects below the lid (Fig. 38-10). Vertical tension should be supported with periosteal sutures that anchor the weight of the flap securely to the nasofacial sulcus.

Figure 38-10. Cheek advancement. (A) Medial defect below the lid margin. (B) Periosteal suspension suture placed in the nasal bone secures the flap and removes tension from the lid. (C) Lid snug against globe upon maximal tension postoperatively. (D) Tension-free flap incisions obscured 2 weeks postoperatively.

Island pedicle V–Y advancement flaps are also useful for medium-sized defects below the lid margin when minimal undermining is needed, but must be robustly suspended to the periosteum to offset vertical tension. Suspension

sutures are placed far back from the flap margin so that the flap supports the lid with maximal tension on upward gaze. Island flaps are best designed carefully with a slightly undersized width so that tissue is pushed toward the lid with lateral tension vectors, and pin-cushioning is minimized.

Defects confined to the outer canthi are best repaired with inferiorly or superiorly based transposition and rotation flaps that utilize the skin reservoirs of the upper lid crease, temple, and lateral cheek areas.²¹ Suspension sutures can be placed in the orbital periosteum to support the canthal tissues and protect against ectropion. Bilateral rotation flaps can be used for defects above and below the canthal apex. Flaps should be suspended to the lateral canthal tendons to recreate the canthal angle. Full-thickness skin grafts, including adjacent tissue Burow's grafts, can be used when needed, as long as they are adequately sized and supported with pecking sutures to prevent distraction of the lid away from the globe.

UPPER LID

Defects involving the skin and muscle of the upper eyelid are routinely repaired with flaps and grafts fashioned from the adjacent or contralateral eyelid (Fig. 38-11). Flaps and grafts such as these provide tissue and robust vascularity for rapid wound healing and can often be hidden in natural creases. Blepharoplasty-type advancement flaps based on the lid crease can be ideal for superficial defects on the upper lid where the incision lines are made along the natural lid crease and redundant skin and muscle of the crease can be easily mobilized into defects (Fig. 38-12). Just as in a simple blepharoplasty, incisions are kept lateral to the caruncle and may extend beyond the lateral canthus when hooding is present. Full-thickness defects of the upper lid often require the expertise and management of an oculoplastic surgeon to preserve the functional components of the upper lid.

Figure 38-11. Defects on the upper lid can often be repaired with traditional or blepharoplasty-type advancement flaps with incisions along the lid crease. Transposition flaps can be useful for large defects.

Figure 38-12. Blepharoplasty advancement flap. (A) Defect on the upper lid extending to the margin. (B) Flap incised with redundant cones removed from the upper lid crease. (C) Flap in place postoperatively. No sutures are placed along the lid margin to avoid irritation and corneal abrasion. (D) Tension-free flap 1 week postoperatively.

MEDIAL CANTHUS

The complex anatomy of the medial canthus creates distinct challenges for the periocular surgeon.^{29,30} Though it may worsen with age, the propensity of medial canthal skin to form a web is fairly constant. Webbing across the canthus occurs readily if not actively prevented, due to its concave contour, the need for vertical movement of the brows, and the thin mobile skin inside the orbital rim adjacent to the relatively thicker bound skin of the cheek and nose. Fundamental principles of reconstruction in the medial canthus that

minimize risks of webbing include designing flaps within the canthal subunits, sizing flaps, and grafts adequately to cover the concavity of the canthi and accommodate vertical movement of the muscles of facial expression, and suspending flaps to the periosteum and canthal support tissues to direct tension.¹²⁻¹⁴ Conceptually, the subunits of the medial canthi are defined by the attachments of the orbital rim that separate the more thin mobile skin inside the orbit from the thicker bound skin of the cheek and nose, and the horizontal apex of the medial canthus (Fig. 38-13).¹⁴ Combining flaps within the canthal subunits and suspending them to the canthal support tissue is a cornerstone of repairing canthal defects to reliably avoid webbing.¹²

Figure 38-13. Medial canthal subunits: Combining flaps within the canthal subunits and suspending them to the canthal support tissue (*) is a cornerstone of repairing canthal defects to reliably avoid

webbing. Skin inside the orbital rim is thin and mobile compared to thicker bound surrounding skin, easily contracting with tension.

Owing to its innate concavity and complex anatomy, second-intention healing and skin grafting are often used for defects in the medial canthus.^{31–33} Second-intention healing is ideal for small, superficial defects near the apex of the canthus. Full-thickness skin grafts are also commonly used to repair medial canthal defects, and even for deeper defects particularly when tumor surveillance is a high priority.

Nevertheless, flap repairs in the medial canthus often optimize outcomes and help avoid the drawbacks and limitations of grafts and second-intention healing. For defects located at or superior to the canthal apex, hatchet-type rotation flaps based on the glabellar skin are ideal (Fig. 38-14).³⁴ Incisions can be obscured in natural rhytids, and the tissue reservoir is ample, so flaps rotate freely into the canthus. The flap base can provide bulk for deeper defects or can be thinned for superficial defects, and can be easily suspended to the canthal tendon to preserve the natural canthal concavity. The high degree of mobility and minimal visible scarring make this flap a workhorse in this area. Glabellar rotation flaps can be combined with a number of inferiorly based flaps to repair larger defects that include the superior aspect of the medial canthus.³⁵ The canaliculi can be probed and canalized with care not to traumatize them to ensure patency when indicated.²⁸ Damage to the lacrimal drainage system may require reconstructing; however, many patients, particularly elderly patients with dry eyes, benefit from the disruption and do not require repair.

Figure 38-14. Hatchet flap. (A) Medial canthal defect at and above the canthal apex. (B) Flap based on the ample glabellar reservoir undermined in the mid fat with incisions placed in preexisting rhytid. (C) Suspension suture placed in the medial canthal tendon and 1 cm from the flap edge. (D) Canthal concavity preserved with maximal tension postoperatively.

Island pedicle (V–Y type) advancement flaps suspended to the periosteum or canthal tendon can be ideal for superficial and deep defects located at or below the canthal apex, including deeper defects that breach the orbital septum (Fig. 38-15).^{36–41} Incision lines can be partially obscured in the shadow of the nasofacial sulcus, and the medial cheek skin moves readily above the malar fat pad. Island pedicle flaps can be suspended to the periosteum or canthal tendon to preserve the contour of the canthus. Island pedicle flaps are advantageous in this area because they have immense mobility with minimal undermining, do not require removal of redundant

cones, and are easily and efficiently designed and executed. These flaps are best designed with adequate length to avoid webbing, yet slightly undersized width to avoid pin-cushioning. Like blepharoplasty surgery, when the orbital septum is breached, the flap is mobilized and suspended into place without suturing the orbital septum. The septum is left to heal naturally to avoid tethering and lid retraction with wound contraction.

Figure 38-15. IPF with canthal suspension. (A) Medial canthal defect at and below the canthal apex (arrow indicates medial canthal tendon and orbital fat pad). (B) Flap based on the mobile malar fat pad with suspension suture placed in the medial canthal tendon and 1 cm from the flap edge. The orbital septum is left to heal without suturing to prevent tethering. (C) Tension-free flap with concavity preserved and punctum in the lacrimal lake 2 weeks postoperatively.

Larger defects can be repaired with a combination of rotation, transposition, or advancement flaps to avoid webbing. Bilateral rhomboid

transposition flaps that direct redundant cones toward the canthus to avoid webbing are useful for larger medial canthal defects (Fig. 38-16). The largest medial canthal defects may require full-thickness skin grafts from remote sites or two-stage interpolation flaps from the forehead to provide adequate tissue coverage.

Figure 38-16. Double rhomboid flaps. (A) Large defect involving the canthus to the nasal root. (B) Two rhomboid transposition flaps are designed above and below the defects. (C) Well-healed flap without webbing 5 years postoperatively.

For smaller defects close to the lid margins, lid advancement flaps based on lax lid skin are ideal (Fig. 38-17). Incisions are made close to the lash line and advanced horizontally to minimize risk of webbing. Suspension sutures can be useful to support flaps during wound contraction, even for the smallest of defects.

Figure 38-17. Lid advancement flap. (A) Vertically oriented defect below the medial canthal apex. (B) A subciliary incision is made, flap undermined, and suspension suture placed in the medial canthal tendon. (C) Canthal suspension suture is gently tightened with graduated tension. (D) Concavity is preserved with no vertical tension postoperatively.

Suspension sutures can be placed in the periosteum or the medial canthal tendon.^{12–14} An intimate knowledge of the vascular anatomy of the medial canthus and a well-developed tactile sensitivity are essential for precise placement. Suspension sutures are placed through the medial canthus by advancing the needle through the periosteum or canthal tendon, entering and exiting at a shallow angle, and avoiding excessively deep penetration through the underlying lacrimal sac. Flaps are secured at the concavity within the canthus.

FULL-THICKNESS EYELID REPAIRS

Once the full thickness of the eyelid is involved, the reconstructive technique must provide an adequate mucosal surface to replace the missing posterior lamella, as well as the anterior lamella. The conjunctival fornices are generous both medially, and more so laterally, allowing significant central displacement with large wedges that can be reapposed once the lateral canthus and septal attachments are released. For even larger excisions, the tarsal plate and mucosal surface are provided by the release and advance of the upper portion of the inner aspect of the upper eyelid via the supremely versatile Hughes flap. The loss of the medial canthal ligaments and canaliculi, with resultant epiphora, will require a complex multistage reconstruction by oculoplastic and lacrimal surgeons. The primary repair should aim to reconnect the medial edges of the upper and lower lids back together and to draw the reformed medial canthus to the posterior lacrimal crest. The anterior lamella can then be covered with any of the above techniques.

In deciding the best way to reconstruct the tissue lost following tumor extirpation, it is traditional to divide the periocular area involved into subunits and then consider the options for progressively larger defects in that area.

PRIMARY LID REPAIRS: DIAGONAL SUTURE TECHNIQUE

Primary lid repair techniques apply to all full-thickness defects of the lid margin, either alone or in combination with other techniques required for larger defects (Fig. 38-18). Robust and meticulous approximation of the lid margin along the x-, y-, and z-axes is essential to prevent notching and provide the best functional and aesthetic outcomes.⁴² Historically, multiple horizontal tarsal sutures combined with multiple marginal sutures have been used to provide strength and alignment. Because marginal sutures are often bothersome to patients and have the potential to abrade the cornea, a diagonal tarsal suture technique sine marginal suture provides robust strength as well as precise alignment without the need for marginal sutures.^{6,43}

Figure 38-18. Primary lid repair: Diagonal tarsal suture sine marginal sutures. (A,B) Full-thickness defect involving medial the lid margin. (C) Primary lid closure postoperatively, robustly approximated, and accurately aligned without need for marginal sutures. (D) Lid snug against the globe without notching 3 months postoperatively.

To confirm that the tarsal edges can be directly opposed, the medial and lateral ends of the wound are grasped with fine forceps to assess the tension required to bring the edges together. An overlap of 2 to 3 mm should be possible with moderate tension to allow easy closure. If the tension is too great, a lateral canthotomy and cantholysis can be performed to provide mobility of the lid for tension-free closure. For larger defects, the canthotomy may be extended to a Tenzel semicircle rotation flap.²⁶

Technique

Local anesthetic drops are applied to the conjunctival fornix, followed by an injection of local anesthetic containing epinephrine into the conjunctival lid margin, avoiding the marginal arcades.

Before the margin is closed, ensure the opposing tarsal plates have been cut perpendicular to the eyelid margin. This is essential to preserve the curve of the lid margin and avoid distortion or notching. The tarsal plate is recut if necessary.

The tarsal plates are reapposed with two sutures, a diagonal vertical suture and a horizontal inferior suture (Fig. 38-18). Each suture must take a deep bite of the tarsal plate. The superior diagonal suture is passed first into the right-hand tarsal plate 2 mm inferior to the lid margin and 2 mm inside to the cut edge. The tip exits just deep to the conjunctiva at the uppermost aspect of the tarsal plate. This diagonal pass is most easily achieved by grasping the tarsal plate horizontally at its midpoint. The second pass of the superior diagonal suture is into the left-hand tarsal plate. This is most easily achieved by backhanding the suture, grasping the tarsal plate vertically and entering the tarsal plate just deep to the conjunctiva at the uppermost point of the tarsal plate and passing to exit the anterior surface of the tarsal plate 2 mm inferior and 2 mm inside the cut edge. This superior suture is clipped and neither tied nor cut to allow easier access for the next suture. The second horizontal suture is then passed through the tarsus horizontally at the inferior border of the tarsal plate with a generous bite of each tarsal plate, remaining deep to the conjunctiva. This can be tied and cut. The clip from the superior diagonal suture is released and the suture tied and cut. The apposed edges of the lid margin should be in perfect apposition. The closure of the posterior lamella should now be complete. The anterior lamella is then closed in a layered manner with deep sutures closing the orbicularis and skin sutures beginning at the subciliary line. Topical antibiotic ointment is applied to the eye and sutures daily until the skin sutures are removed in 6 days. Ice packs are applied for comfort and to reduce swelling.

LATERAL CANTHOTOMY AND CANTHOLYSIS

Perfect apposition of the lid margin without tension is essential to ensure the lid margin is restored. When the tension on the lid margin exceeds the limits

of a primary lid closure, a lateral canthotomy and cantholysis can be performed to release the lid margin and allow a tension-free closure and prevent notching, torsion, or dehiscence of the eyelid (Fig. 38-19). The limits of a primary closure can be evaluated by approximating the edges of the defect with forceps. Once the cantholysis releases the lid enough to approximate the edges of the lid margin without tension, a primary lid closure can be performed in the usual manner.

Figure 38-19. Primary lid repair with cantholysis. (A) Full-thickness defect exceeding the limits of primary lid closure. (B) Primary lid closure with lysis of the lower canthal tendon to relieve tension on the wound edges (note the lid margin robustly approximated and accurately aligned without need for marginal sutures). (C) Lid margin precisely aligned without notching 2 weeks postoperatively.

Technique

The incision from the lateral canthal angle is marked to extend laterally and vertically following the curve of the lower eyelid (for upper lid defects, this curve is reversed to follow the upper eyelid). A small primary skin incision is made with a #15 scalpel blade from the angle of the lateral canthus following the markings for 8 mm. Westcott's scissors are used to release the firm lateral canthal attachment of the lower lid with a canthotomy passing through the inferior crus of the lateral canthal tendon. A pocket is made with the scissors on each side of the septum, and then with the lid under medial tension; the tip of the scissors is used to feel for the tight septal fibers by drumming across them. The cantholysis can then be progressively released by making small nibs with the scissors until the wound can be easily closed. An overlap of 2 mm represents perfect tension. The tarsal plate is then closed primarily with a standard diagonal suture technique and the skin and muscle of the primary defects are closed in a layered manner. As the lateral incision is pulled medially, it usually closes automatically and does not usually require a suture.

TENZEL SEMICIRCLE ROTATION FLAP

Full-thickness defects of the lid margin that are too large to repair primarily with a cantholysis procedure can be reconstructed with a semicircle flap described by Richard Tenzel (Fig. 38-20).²⁶ The Tenzel flap combines a modified lateral advancement-rotation flap with canthotomy and cantholysis procedures to repair defects up to 75% of the upper or lower lid margins. The Tenzel semicircle flap is ideally performed when there is at least 2 mm of tarsus remaining, but can be performed successfully with less. There is focal absence of lashes laterally, but this is not a functional concern and rarely bothers patients. Surgeons performing Tenzel flaps should be familiar with canthal anatomy and seek experience and training in more advanced periocular surgery. Defects that are too large to be repaired with a Tenzel semicircular flap are best repaired with a two-stage Hughes tarsoconjunctival flap from the upper lid.⁴⁴

Figure 38-20. Tenzel semicircle flap. (A) Large full-thickness defect involving the upper lid with semicircle rotation flap drawn inferiorly. (B) Semicircle flap incised and rotated to allow closure of the upper lid defect. (C) Semicircle flap and primary lid closure sutured in place postoperatively.

Technique

Incisions are marked from the lateral canthal angle to extend laterally and vertically following the curve of the eyelid. At the apex, the mark begins curving downward forming a semicircle. The average diameter of the semicircle is approximately 1 to 2 cm and in practice may not be a true semicircle. A skin incision is made with a #15 scalpel blade, initially following only the lateral and vertical curves of the Tenzel flap. The flap can be extended later if required. The firm attachment of the lower lid is released with a canthotomy passing through the inferior crus of the lateral canthal tendon with Westcott scissors. The scissors are then used to make a pocket on each side of the septum, and then with the lid under medial tension use the tip of the scissors to feel for the tight septal fibers by drumming across them. The cantholysis is then progressively increased until the wound can be easily closed. Care is taken not to disrupt the upper limb of the canthal tendon. The flap is then rotated and sutured into place and the primary defect closed using the standard diagonal tarsal suture technique. A canthal suspension suture is sometimes placed at the lateral canthus to provide additional support. As the lateral Tenzel flap is pulled medially, it usually closes automatically, and

often only a small number of interrupted sutures are required to close the skin.

POSTOPERATIVE CONSIDERATIONS

Immediately following periocular surgery, erythromycin ophthalmic ointment is applied to the eye and suture line, followed by a light pressure dressing and ice packs for 24 hours to minimize edema. Pressure dressings are applied carefully to wounds so that excessive pressure is not placed on the globe. Defects close to or involving the lid margin are often dressed with an eye pad placed over a closed lid and covered with an eye shield to protect the eye from trauma. Postoperative dressings that are tension bearing can help offset the tension associated with swelling and administration of local anesthetics. Patients are often observed for a period postoperatively before discharge to ensure hemostasis and comfort.

Close observation is essential in the postoperative period to identify potential complications early and ensure success. Patients are instructed to contact their surgeon directly in the case of bleeding or acute pain after surgery. Early recognition and management of serious bleeding is essential to identify and treat potential retrobulbar hemorrhage, which requires an emergency canthotomy to prevent irreversible blindness. Follow-up is generally recommended 24 hours after surgery for complex lid repairs. Complex wounds with full-thickness lid loss that will be transferred to the care of an oculoplastic surgeon may require a temporary tarsorrhaphy to ensure the cornea is protected until definitive repair ([Fig. 38-21](#)).

Figure 38-21. Modified Frost suture: A suture is placed through the meibomian gland orifice of the lower lid margin, following the curve of the needle, and exiting the adjacent lid margin through the meibomian gland orifice. The suture is then secured to the forehead with steri-strips.

TEMPORARY TARSORRHAPHY

Numerous temporary tarsorrhaphy procedures have been described that effectively protect the cornea for a short time period postoperatively. A simple tarsorrhaphy may be performed by passing a 4-0 polypropylene suture through a plastic or petroleum gauze bolster before entering the upper lid, entering 4 mm from the margin and exiting through a meibomian gland orifice. The needle is then passed through the opposing lower lid, entering through a meibomian gland orifice and exiting through the lower lid skin 4 mm or so from the margin. The needle is then passed through the tubing or bolster exiting 1 cm laterally. The needle is then passed through the skin in

the same manner, exiting through the meibomian gland of the lower lid and then through the upper lid and upper bolster in the same manner. The suture is then gently secured to close the lid comfortably.

MODIFIED FROST SUTURE

The Frost suture is a useful technique for opposing downward tension vectors and preserving or restoring the position of the lower eyelid (Fig. 38-21).¹⁸ A 4-0 monofilament suture is passed through the lower lid tarsal plate, entering and exiting the lid margin through the meibomian gland orifice while following the curve of the needle. The suture is then secured to the forehead with steri-strips. The suture may be left in place for up to a week, or slightly longer in the case of ectropion repair. If possible, the Frost suture is placed either medial or lateral to the mid-pupillary line to prevent visualization during natural forward gaze.

COMPLICATIONS

The aim of all techniques is to restore the eyelid without causing distortion or ectropion to the lid margin. Complications can occur even in the best of circumstances. Some common complications include bleeding, infection, hematoma, chemosis, epiphora, dry eye, suture granuloma, trichiasis, lid notching, scleral show, asymmetry, ectropion, and webbing. Even mild ectropion can cause significant epiphora and discomfort and may require a slit-lamp examination to evaluate for corneal abrasion. If this occurs in the immediate perioperative period, a temporary bandage contact lens can sometimes be placed to protect the cornea until offending sutures are removed, or the causative factor is corrected. Complications that occur after wound contraction is complete, such as ectropion or webbing, may require surgical revision. Ectropion and webbing are best prevented with fundamental surgical techniques and tension management, including appropriate flap design, suspension sutures, and Frost sutures when indicated.⁹ Both ectropion and webbing tend to occur 2 to 4 weeks postoperatively during maximal wound contraction. Correction usually requires flap revision and canthopexy procedures. Ideally, patients undergoing extensive surgery around the eye should have a preoperative

ocular examination and consultation with an oculoplastic surgeon to ensure a smooth transition of care if needed.

Ectropion Repair

Simple cicatricial ectropion in the absence of pre-existing lid malposition can be corrected with a flap or graft that lengthens the anterior lamella combined with canthal suspension (Fig. 38-22).⁴⁵⁻⁴⁹ Early intervention is best, before wound contraction is severe. Repair begins with excising the scar and estimating the size of the defect on maximal stretch of the lower lid with upward traction. The defect size can be estimated by blotting the area with a sterile nonadherent gauze pad. The flap or graft can then be appropriately designed to provide ample coverage on maximal stretch. Pushing flaps, such as inferiorly based rhombic transposition flaps or superiorly based Tripier-type transposition flaps combined with a lateral canthopexy, are often straightforward and satisfactory.^{47,48} Full-thickness skin grafts sized adequately with the lid on full stretch, tacked down, and combined with a canthopexy suture or a full lateral tarsal strip are reliable for even some of the most severe ectropion.⁴⁹ A modified Frost suture is generally beneficial to counteract the downward traction and is left in place for 7 to 10 days.

Figure 38-22. Ectropion repair. (A) Low-lid ectropion 3 weeks after the repair was delayed following Mohs surgery. (B) Oversized full-thickness skin graft designed with lid on maximal stretch. (C) Ectropion repaired 2 weeks postoperatively.

Web Repair

Webbing of the medial canthus can usually be repaired with a simple Z-plasty procedure that provides vertical length to constricted skin along the canthal concavity (Fig. 38-23).⁵⁰⁻⁵² Z-plasty repair is performed by incising along the length of the web constriction with a #15 scalpel blade. A 60-degree flap is then created on opposing sides of each end of the incision. The flaps are elevated and transposed to create length, resolving the tensional forces that created the web.

Figure 38-23. Z-plasty repair of canthal web: Z-plasty repair is performed by incising along the length of the web constriction with a #15 scalpel blade. A 60-degree flap is then created on the opposing sides of each end of the incision. The flaps are elevated and transposed to create length, resolving the tensional forces that created the web.

CONCLUSIONS

Eyelid repairs are a cornerstone of dermatologic surgery and reconstruction. Knowledge and familiarity with the management of tension is essential, and maintaining tension parallel to the lid margin is of the utmost importance.

Suspension sutures are used frequently for eyelid reconstruction, and a combination of tailored approaches based on individual anatomy yields consistently outstanding clinical outcomes.

CHAPTER 39 Reconstruction of the Nose

Christopher J. Miller

Thuzar M. Shin

Joseph F. Sobanko

Eduardo K. Moiola

Jeremy R. Etzkorn

SUMMARY

- The nose is a focal point of the central face, and subtle changes in shape and contour can easily alter a patient's appearance.

- The task of the surgeon is to simulate normal anatomy by restoring the complex topography of the nose and maintaining patent nasal airways.

Beginner Pearls

- The shape of the nose is usually preserved if tension during reconstruction lies over the immobile bones of the proximal and lateral nose, but may be distorted from tension over the flexible cartilage of the nasal tip or the soft tissue of the alar lobule, which lack cartilage.
- The varying texture and thickness of the nasal skin may influence the selection of donor sites for reconstruction.

Expert Pearls

- The skin is most mobile over the root, dorsum, and sidewalls, where there is a layer of subcutaneous fat separating the skin from the underlying muscles of facial expression.
- The arteries run superficial to the nasal musculature, and therefore undermining flaps deep to muscle at the level of the perichondrium or periosteum preserves the vascular supply.

Don't Forget!

- Placing scars in cosmetic subunit junction lines may help to disguise scars, but reconstruction should prioritize preservation and restoration of free margins and contour.
- For the dorsal nasal flap, advancement of cheek skin is aided by undermining the cheek in the subcutaneous fat.

Pitfalls and Cautions

- The complex nasal topography means that caution should be exerted in not overly evert areas with natural creases, such as the nasofacial sulcus and alar groove.
- When recreating the alar groove, inverting sutures or allowing select areas to heal by secondary intention may be helpful.

Patient Education Points

- The complexity of a closure, and the projected intensity of postoperative care, should be considered carefully, particularly in patients with multiple comorbidities.
- The range of options for surgical reconstruction should be addressed with the patient prior to surgical intervention.

Billing Pearls

- Linear closures on the nose are coded using standard repair series.
- Single-stage random-pattern nasal flaps are coded using 14060 or 14061, depending on the flap size.
- The use of suspension sutures may justify coding a linear closure as complex.

CHAPTER 39 Reconstruction of the Nose

INTRODUCTION

The nose is a focal point of the central face, and subtle changes in shape and contour can easily alter a patient's appearance. The task of the surgeon is to simulate normal anatomy by restoring the complex topography of the nose and maintaining patent nasal airways. Several key principles underlie nasal reconstruction.

ANATOMICAL PRINCIPLES

The distal nose is vulnerable to compression

The bony nasal skeleton resists compression, whereas the cartilaginous skeleton and ala may not. Therefore, the shape of the nose is usually preserved if tension during reconstruction lies over the immobile bones of the proximal and lateral nose, but may be distorted from tension over the flexible cartilage of the nasal tip or the soft tissue of the alar lobule, which lacks cartilage (Figs. 39-1 and 39-2).

Figure 39-1. The nasal bone resists compression from tension on the proximal nose, but the mobile cartilages of the distal nose may not. A defect of the proximal nose is reconstructed with a tight linear closure. The nasal bone resists compression, and the shape of the nose is unchanged. (A) Mohs defect. (B) Linear closure. (C) Postoperative appearance with preserved nasal contours. (D) Critical anatomy for nasal reconstruction.

Figure 39-2. Tension over the distal nose can compress and distort the nose. Clockwise from top left: Mohs defect; appearance of columella and nostrils prior to reconstruction; compression of the lateral crus of the left lower cartilage and rightward deviation of the septum; primary closure of nasal wound.

The paired nasal bones brace the proximal dorsum and root of the nose, and the maxillary bones gird the nasal sidewall and sill. These bones converge to form the pyriform aperture, which provides a stable frame for the flexible cartilaginous skeleton and anchors most of the nasal muscles of facial expression. The external nasal skeleton consists of three primary cartilaginous structures: (1) the septal cartilage; (2) the paired upper lateral cartilages; and (3) the paired lower lateral cartilages.

The septal cartilage determines the projection and rotation of the nose, separates the right and left nasal cavities, and forms the medial boundary of the internal and external nasal valves. Surgical removal of the distal septal

cartilage or compression during reconstruction decreases nasal projection. Lateral deviation of the septum from undesirable tension vectors during reconstructive surgery can constrict the nasal valves and compromise breathing.

The paired upper lateral cartilages support the lateral nasal sidewall. Their caudal margin forms the lateral border of the internal nasal valve, so airway compromise may occur with the removal or compression of the upper lateral cartilage. The septal cartilage and paired upper lateral cartilages are anchored to bone and are therefore relatively resistant to compression.

By contrast, the lower lateral cartilages do not articulate directly with bone and are vulnerable to compressive forces. Compression of the lower lateral cartilages, which provide structure and projection to the nasal tip and support to the external nasal valve, affects the shape of the nasal tip and can compromise breathing.

The topography of the nose creates shadows and reflections that delineate cosmetic subunits

The nasal surface transmits the shapes of the underlying osseocartilaginous skeleton and soft tissues, resulting in shadows and reflections that divide the nose into the following cosmetic subunits: the tip, dorsum, root, sidewalls, alae, and soft triangles.¹ Scars at the junctions of these cosmetic subunits are frequently less conspicuous (Fig. 39-3). The naturally occurring concavities on the nose are the slight break at the supra-tip (corresponding to the scroll region, where the lower lateral cartilages connect with the upper lateral cartilages); the alar groove (corresponding to the inferior margin of the lateral crus of the lower lateral cartilage and the underlying nasal muscles); the faint shadow at the soft triangles (corresponding to the soft tissue distal to the caudal margin of the domes of the alar cartilages); and, occasionally, minimal bifidity of the nasal tip (corresponding to the space between the domes of the lower lateral cartilages). Naturally convex surfaces on the nose are the alar lobule, the nasal tip, and the dorsal nasal ridges. The dorsum and sidewalls have largely planar surfaces.

Figure 39-3. Scars in cosmetic subunit junction lines are inconspicuous. (A) Melanoma *in situ* of the left nasal tip. (B) The defect has been enlarged to include the entire nasal tip subunit. (C) Reconstruction with a paramedian forehead flap. (D) Postoperative appearance with inconspicuous scars in cosmetic subunit junction lines.

Nasal skin has varying thickness, texture, and mobility

The varying texture and thickness of the nasal skin may influence the selection of donor sites for reconstruction. The dorsum, sidewalls, columella, and soft triangles have a thin dermis and a relatively lower density of sebaceous glands. Skin grafts often heal with a reasonable texture match in these locations. By contrast, the thick and sebaceous skin of the tip, alae, and root is often best replaced by more densely sebaceous skin of the forehead and nasolabial folds, if rearrangement of skin immediately adjacent to the defect is not possible. The skin is most mobile over the root, dorsum, and sidewalls, where there is a layer of subcutaneous fat separating the skin from the underlying muscles of facial expression.

The external and internal nasal valves control airflow and must be preserved or restored

Eighty-five percent of the adult population preferentially breathes through the nose, except in times of exercise or when speaking.² The external and internal nasal valves regulate airflow and resistance, and they are vulnerable to collapse from excessive tension or compression during nasal reconstruction or from loss of integrity during oncologic resection.

The external nasal valve controls air passage through the distal nostril. The anatomic boundaries of the external nasal valve are the caudal edge of the upper lateral cartilage superolaterally, the nasal ala and attachment of the lateral crus laterally, the caudal septum and columella medially, and the nasal sill inferiorly.³ Patients who have a highly flexible nasal tip, whose ala collapses with forced inspiration, or who have improved breathing while distracting the ala laterally (Cottle test) are at particularly high risk for external valve collapse.

The internal nasal valve is located immediately superior to the external nasal valve and is the site of the greatest resistance in the human airway. The internal nasal valve is the flow-limiting segment of the nasal airway and contributes approximately 50% of the total airflow resistance for the combined upper and lower airways.² The internal nasal valve is the cross-sectional area bordered by the cartilaginous septum, the caudal margin of the upper lateral cartilage, and the anterior head of the inferior turbinate. The valve angle between the septal cartilage and caudal margin of the upper lateral cartilage is between 10 and 15 degrees in the Caucasian nose, but

tends to be more obtuse and increasingly resistant to collapse in African-American and Asian noses.⁴ During nasal reconstruction, the internal nasal valve is at risk for collapse from deviation of the septum or from compression or weakening of the caudal margin of the upper lateral cartilage.

The nasal skin has a rich and anastomotic arterial blood supply from both the external and internal carotid systems

The facial artery, stemming from the external carotid system, issues the inferior alar artery along the nasal sill, the lateral nasal artery 2 to 3 mm superior to the alar groove, and the angular artery along the nasofacial sulcus. The columella receives its blood supply from paired arteries that branch off the superior labial artery.⁵ The internal carotid system supplies the nasal skin with the dorsal nasal artery (DNA), a terminal branch of the ophthalmic artery.⁵ The external and internal carotid systems communicate where the angular artery anastomoses with the DNA at the medial canthus and where the lateral nasal artery anastomoses with the DNA at the nasal supra-tip. The arteries run superficial to the nasal musculature, and therefore undermining flaps deep to muscle at the level of the perichondrium or periosteum preserves the vascular supply.⁶

PRINCIPLES OF RECONSTRUCTIVE DESIGN

In descending order of importance, principles of aesthetic surgical design include preserving and restoring free margins and contour, placing scars in cosmetic subunit junction lines, and placing scars along relaxed skin tension lines. The free margins of the nasal tip and ala lack support distally, and so are especially vulnerable to displacement from tension vectors that pull up, push down, or compress (Fig. 39-4). Tension vectors that lie parallel to the free margins minimize upward or downward displacement, and low-tension closures of the distal nose can prevent inward compression. The complex nasal contours can be preserved or restored by avoiding excessive tension over the distal nose, by filling defects with skin of similar volume, and by using tacking sutures to bend skin that crosses nasal concavities (Fig. 39-5).

Placing scars in cosmetic subunit junction lines may help to disguise scars, but reconstruction should prioritize preservation and restoration of free margins and contour. The bilobed and trilobed flaps illustrate this hierarchy. Their clover-like scar, which does not conform to cosmetic subunit junction lines, is inconspicuous if it preserves the position of the free margins and nasal contour. Relaxed skin tension lines are irrelevant on the nose, except for the bunny lines at the upper nasal sidewall and the horizontal crease resulting from contraction of the procerus at the nasal root.

Figure 39-5. Contour deformities of the nose are noticeable. Example of distorted appearance in a patient with excessive volume from flap reconstruction.

SECOND-INTENTION HEALING

Second-intention healing has two predictable outcomes: the scar will have a shiny texture, and the scar will contract. Therefore, ideal wounds for second-intention healing are located in areas where the skin normally has a shiny

texture and where scar contraction will not cause anatomic distortion. The shiny scar from second-intention healing is less conspicuous on the smoother skin of the nasal dorsum, proximal sidewalls, medial canthus, and columella. By contrast, shiny scars may contrast against the more sebaceous skin of the nasal tip, ala, and root (Fig. 39-6).

Figure 39-6. Second-intention scars may be conspicuous on sebaceous skin. (A) A small defect in the middle of the convex alar subunit was left to heal by second intention. (B) The shiny, depressed scar is conspicuous.

Scars formed by second-intention healing may also hide in or recreate concavities, such as the alar groove, the alar insertion, and the medial canthus (Fig. 39-7).^{7,8} However, this strategy must be employed judiciously, since scar contraction may cause anatomic distortion or lead to blunting of a previously pronounced concavity. For example, wound contraction at the alar groove may elevate the free alar margin or result in a webbed scar. Contraction after second-intention healing of wounds of the nasal sidewall and medial canthus may pull on the free eyelid margin or cause webbing from tension on the adjacent, loose eyelid skin.

Figure 39-7. Second-intention healing of wounds in concavities often heals inconspicuously. (A) A shallow wound of the alar groove was left to heal by second intention. (B) The scar hides in the naturally concave alar groove.

The likelihood of anatomic distortion and webbing is greater for deep wounds spanning the concave junction between cosmetic subunits. The ideal defect to minimize distortion from second-intention healing is shallow, with surrounding skin that is stiff and supported by a strong nasal skeleton. Patients should expect evolving color and volume of the scar. Scars that are initially pink and hypertrophic usually mature to a hypo- or hyperpigmented color with a flatter contour.

PRIMARY CLOSURE

Primary closure is a side-to-side approximation of the edges of a wound. Tension lies along a single vector running perpendicular to the long axis of the wound, is greatest at the center, and decreases toward the apices. To minimize standing cones and to maintain normal contour, the ideal angles at the apices of a fusiform excision are <30 degrees, which requires a length:width ratio of 3:1 or greater. The tight, relatively immobile skin of the

distal nose usually requires a length:width ratio of 4:1 or 5:1 (Fig. 39-8).⁹ Assuming proper design, the orientation, location, and tension of fusiform excisions on the nose are the main influences on an aesthetic outcome. The orientation of the fusiform excision determines the direction of the tension vectors. Horizontally oriented fusiform excisions (e.g., in the alar groove) predictably pull up on the free margins, potentially resulting in an upward turn of the nasal tip or alar lift. To avoid malposition of the free margins, fusiform excisions on the nose are best oriented vertically or obliquely, so that tension vectors run parallel to the free margins and avoid an upward pull. Distortion is still possible, particularly on the ala, where elongation of the central axis after wound closure may result in downward push of the free margin.¹⁰

Figure 39-8. Primary closures on the nose often require a length:width ratio of $>4:1$ to avoid preserve contour. (A) Depressed scar of nasal tip with standing cones at each apex from insufficient length:width ratio. (B) The scar was excised and revised with a length:width ratio of $>4:1$. (C) Contour is restored and the scar is less conspicuous.

The tension of a fusiform excision may compress and distort the distal nose. If the center of the fusiform excision (i.e., the area of the highest tension) resides over the proximal and lateral nose, the underlying bones resist compression. However, compression is expected when the greatest tension lies over the nasal tip and ala. Tight closure of vertically oriented fusiform excisions over the distal midline nose (especially if tension is distal to the anterior septal angle) may flatten the nasal tip and cause flaring of the nostrils. Tight wounds on the distal paramedian nose and ala may compress the nostrils and compromise breathing.

The location of the primary closure may determine its effects on nasal symmetry, free margin position, and contour. Vertically oriented closures of the midline tip and dorsum usually cause symmetric changes to each side of the nose. By contrast, high-tension paramidline vertical closures may cause asymmetry from downward displacement of the ipsilateral alar margin and upward pull of the contralateral alar margin. Horizontally oriented fusiform excisions may not pull up on the tip or ala if they are small and located on the proximal dorsum or sidewall and nasal root. Primary closures that cross the concavities of the alar groove or the root of the nose may result in webbed scars that distort contour.

SKIN GRAFTS

Skin grafts lack an intrinsic blood supply, so their survival depends on inosculation with the blood vessels of the wound bed. Thicker skin grafts have a greater metabolic demand and an increased risk for failure. To optimize survival, most skin grafts are harvested with epidermis and dermis but minimal to no subcutaneous fat. Consequently, most skin grafts have sufficient volume to restore contour only for shallow wounds with a base of soft tissue over the perichondrium or periosteum. Skin grafts for deep wounds will result in depressed contour or a skeletonized appearance of the nose (Fig. 39-9).

A

B

C

D

Figure 39-9. Skin grafts usually require soft tissue over the cartilages to preserve nasal contour. (A) Example of skeletonized cartilages from a skin graft without sufficient soft tissue at base of wound. (B–D) Example of preserved nasal contour from a graft with sufficient soft tissue over the lower lateral cartilages.

Donor skin should match as closely as possible the color and texture of nasal skin. The forehead and nasolabial folds have a high density of sebaceous glands, but these sites are used infrequently because of the visibility of the donor scars. Donor sites preferably leave scars in less conspicuous locations. Less noticeable donor sites for smaller nasal grafts include the preauricular skin between the tragus and sideburn, which has small vellus hairs closely simulating the distal nasal skin; the glabellar skin, where a vertically oriented closure may be easily hidden; the postauricular skin, which has a thin dermis that nicely matches the skin of the dorsum and proximal nose; and the conchal bowl, whose stiff and sebaceous skin resembles the skin of the tip and ala. Larger nasal wounds require more generous donor sites, such as the supraclavicular skin, which often has similar actinic damage to the nose.

Grafts may be variably noticeable, depending on the normal texture of an individual's nasal skin. Skin grafts usually are less conspicuous when they replace the thin, nonsebaceous skin of the dorsum, sidewall, and columella (Fig. 39-10). By contrast, grafts are usually readily apparent on thick, densely sebaceous skin of the tip and ala (Fig. 39-11). The density of sebaceous glands varies among individuals, so skin grafts may blend in well for patients with less sebaceous skin.

A

B

Figure 39-10. Skin grafts often have a better match over the less sebaceous regions on the nose. (A) Shallow defect over the less sebaceous dorsum. The wound was repaired with a full-thickness skin graft. (B) Postoperative appearance with relatively inconspicuous graft scar.

Figure 39-11. Grafts on the more sebaceous distal nose are often noticeable.

Full-thickness wounds of the alar margin, soft triangle, and columella may require composite grafts, which contain both skin and cartilage. Composite grafts have an especially high risk for failure, due to their high metabolic demand. As a result, composite grafting is usually limited to wounds less than a centimeter in diameter. The root of the helix is a common donor site for composite grafts.

FLAPS

Advancement Flaps

Advancement flaps have a random-pattern blood supply and are useful for wounds that could be closed with a fusiform excision, except one of the standing cones falls in an unfavorable position. As noted in the section on primary closure, fusiform excisions on the nose usually require a vertical orientation to prevent lifting the free margins. The superior standing cone can usually be excised freely, but the inferior standing cone may encroach upon the margin of the ala and tip. In these instances, an advancement flap maintains tension along the same single vector as the primary closure but displaces the inferior standing cone to a more favorable position at the cheek or columella.

For wounds of the lateral nose, an advancement flap (Burow's flap) may shift the inferior standing cone away from the ala to the nasolabial fold. This unilateral advancement flap is ideal for wounds located entirely superior to the alar groove, because the lateral scar may be completely disguised in the nasolabial fold, and the skin can be advanced with a superomedial vector (Fig. 39-12). If the wound involves the alar groove, a transposition flap is usually preferable, because attempting to advance the cheek skin inferomedially usually lifts the ala. For wounds of the paramidline, an advancement flap may extend the scar medially and shift the inferior standing cone away from the soft triangle to the columella (Fig. 39-13).¹¹

Figure 39-12. Unilateral advancements flaps are useful to repair defects of the nasal sidewall. (A) Mohs defect of the right nasal sidewall. A vertically oriented fusiform repair would encroach on the alar

rim. (B) Immediate postoperative appearance of a unilateral advancement flap. The flap is designed to disguise the horizontal incision in the alar groove, and the inferior standing cone is displaced to the nasolabial fold. (C) Aside from the telangiectasias, the scar is minimally apparent.

Figure 39-13. (A) An “east–west” advancement flap is designed to displace the inferior standing cone to the midline nose during the repair of this tall, paramedian defect. (B) Appearance immediately postoperatively. The wound tension causes temporary alar flare, but the nasal bone and septal cartilage resist compression. (C) Postoperative appearance at 1 week. (D) Longer-term follow-up.

This unilateral advancement flap is limited to small wounds, because excising too much skin from the narrow columella can give the nose a pinched appearance.

Rotation Flaps

Rotation flaps distribute tension across multiple vectors to avoid the distortion that would occur from the single tension vector of an advancement flap. The hallmark of a rotation flap is the arciform incision used to mobilize the surrounding skin. Rotating the flap into the primary defect creates a secondary defect along the arciform incision. Tension is distributed with multiple vectors along both the primary and secondary defects. Three common nasal rotation flaps include the dorsal nasal rotation flap, the spiral flap, and the Peng flap.

Dorsal nasal rotation flap

The dorsal nasal flap (DNF) is an axial rotation flap based on the DNA (Fig. 39-14).^{6,12} While the DNF may repair full-thickness defects¹³ and alar defects,¹⁴ it is most commonly used to reconstruct partial-thickness defects on the nasal tip or dorsum. The flap recruits skin from more lax areas of the proximal and lateral nose, allowing reconstruction of moderately sized distal defects without nasal distortion. Defects with a longer vertical axis are ideal for the DNF, since the flap's redundant cone also occurs in this direction. Laterally based bilobed flaps may be better suited for distal midline and paramedian nasal defects with a longer horizontal axis.

A

B

C

D

Figure 39-14. Dorsal nasal rotation flap. (A) A dorsal nasal flap is designed to repair this tall, distal nasal defect. (B) Intraoperative photo demonstrating the planes of dissection. The dorsum and tip are elevated superior to the perichondrium. The root and glabella are dissected in the supramuscular plane.

(C) Immediate postoperative appearance. Note the relative preservation of the shape of the nose. (D) The scar is minimally apparent.

The curvilinear arc of the flap takes off from the distal edge of the defect. Taking off from the proximal defect requires excessive advancement of the flap, which may lead to undue tension or nasal tip distortion. The arc sweeps from the distal defect across the lower nasal tip or cephalic border of the soft triangle and alar crease to the nasofacial sulcus, then continues cephalically to the medial canthus and transverse glabellar crease. A back-cut along the contralateral transverse glabellar crease may improve flap mobility, but it should preserve at least 7 mm of skin near the contralateral medial canthal tendon to protect the DNA. If the flap reaches the defect without tension, extension into the glabella is unnecessary.

The flap is elevated in a caudal to cephalic direction. The distal flap over the tip, sidewalls, and dorsum is elevated in the supraprimerichondrial plane deep to the nasalis muscle. At the root of the nose, the dissection shifts to a more superficial plane immediately above the procerus muscle. To improve the mobility of the flap, undermining extends toward the contralateral medial canthus, taking care to maintain the undermining plane just above the periosteum and preserve the DNA.

When the undermined flap slides toward the defect with minimal tension or nasal distortion, the redundant cone is removed. A vertically oriented standing cone decreases the size of the pedicle, but minimizes elevation of the tip and ala. A more horizontally oriented standing cone maximizes the size of the pedicle, but may result in the elevation of the tip or ala. Excising the standing cone to perichondrium will usually transect the lateral nasal artery. If the surgeon fears that the DNA may not supply sufficient blood to the distal flap, the lateral nasal artery may be preserved by excising the standing cone in the subdermal plane. However, the excess soft tissue may result in a bulkier contour.

The key suture for the DNF approximates the leading edge of the flap to the most distal or caudal portion of the defect. Minimal distortion of the nose should occur after placing this suture. The second key suture re-approximates the secondary defect along the nasofacial sulcus. Advancement of cheek skin is aided by undermining the cheek in the subcutaneous fat, immediately superficial to the levator labialis superioris alaeque nasi. Additional sutures are placed along the remainder of the flap, with careful attention to evert the

skin edges, though hypereversion in the nasofacial sulcus should be avoided. If a glabellar incision is made, judicious thinning of the fat and dermis of the glabellar skin to approximate the thickness of the more delicate canthal skin may improve the contour match at the medial canthus. If a glabellar incision is not made, the surgeon may find that a small tissue redundancy may need to be removed by taking a Burow's cone into the canthal area.

Spiral flap

The spiral flap is a rotation flap with a tight arc between 180 and 270 degrees.¹⁵ The flap is ideal for defects of the alar groove and lateral nasal tip (Fig. 39-15). Although the flap has a narrow pedicle and slim distal tip, the robust blood supply from the nearby lateral nasal artery keeps the flap viable.

A

B

C

D

Figure 39-15. (A) A spiral flap is designed to repair this small, deep defect of the anterior alar groove. (B) Immediate postoperative appearance. (C) Inconspicuous scar with longer-term follow-up. (D) The Peng flap is a bilateral rotation flap used to repair defects of the nasal tip and distal dorsum.

The take-off point for the arciform incision is at the distal and medial aspects of the nasal defect. The arc extends in a three-quarter circle ending at the nasofacial sulcus. The flap is elevated with or without the transverse nasalis and rotated like a spiral toward the defect. The thin distal tip of the flap bends like a hook to recreate the alar groove. Partial necrosis of the thin distal tip may occur, but second-intention healing along the alar groove still results in a reasonable aesthetic outcome. The secondary defect along the nasal tip and sidewall is sutured with a layered closure.

Peng flap

The Peng flap is a bilateral rotation flap used to repair defects of the nasal tip and distal dorsum (Fig. 39-15D).¹⁶ It can be conceptualized as a bilateral DNF. The take-off points of rotation flaps affect biomechanics: initiating the arciform incision from the distal defect makes the flap tips narrower and more vulnerable to necrosis, but the flaps require minimal distal advancement to reach the distal defect. Pivotal restraint shortens the flaps as they are rotated, so some upward secondary motion from the nasal tip is expected. Initiating the arciform excision from the proximal defect creates a broader flap tip, but the flap requires more distal advancement to cover the defect. Significant secondary motion may elevate the nasal tip.

Regardless of the take-off points, the flaps are rotated centrally and sutured at the midline nose. A standing cone forms at the superior aspect of the defect and requires excision to restore contour. A secondary defect forms along the lateral aspects of the arciform excisions. Closing the secondary defects may result in flaring of the ala or compression of the lateral crura of the lower lateral cartilages, especially if the flaps are used to repair distal nasal defects.

V–Y island pedicle flaps

V–Y island pedicle advancement flaps differ from the other sliding flaps in that their entire blood supply comes from the flap's undersurface (Fig. 39-16). A triangular-shaped flap is designed with the base of the triangle at the edge of the nasal defect. Incisions are made through the dermis of the two remaining limbs, creating the “island” that gives the flap its name. The skin of the nose is relatively adherent to the underlying cartilage and muscles of facial expression, so the flap may not advance after releasing the dermis. In most cases, the underlying muscle must be incised on one of the flap limbs,

and the flap is undermined deep to the muscle.¹⁷ The skin is released from the superficial aspect of the muscle on the opposite limb, and the flap usually gains enough mobility to advance toward the defect. If the flap is still restrained, the muscle pedicle may need to be partially incised. While incising the muscle on both sides of the flap may increase the mobility, it may threaten the viability of the flap.

Figure 39-16. Example of V–Y island pedicle advancement flap. (A) A small, deep defect on the anterior alar groove. (B) The wound is extended in a column to the alar margin, and a V–Y advancement flap is incised in the alar groove and free margin. (C) The flap is advanced anteriorly on its pedicle, leaving a secondary defect along the posterior alar groove. (D) Appearance immediately after surgery. (E) Postoperative appearance with inconspicuous scar and preserved nasal contour.

Once the flap is sufficiently mobilized, a key suture advances the leading edge of the flap toward the defect. Secondary motion is expected, particularly if the flap is still restrained. The secondary defect at the trailing edge of the flap is closed primarily, resulting in a suture line that resembles a “Y.”

To avoid elevation of the tip and ala, the flap is usually designed to recruit skin along a horizontal vector from the nasal sidewall or lateral ala toward the midline. V-Y flaps may also be designed to move from superior to inferior, though elevation of the tip and ala is then more likely.

Transposition Flaps

Transposition flaps avoid distortion and compression of the distal nose by displacing the tension to the tissue reservoirs on the proximal and lateral nose and by keeping tension vectors parallel to the margins of the tip and ala (Fig. 39-17).¹⁸ They are especially useful when tension at the primary defect precludes primary closure or a sliding flap.

Figure 39-17. Tissue reservoirs on or near the nose. The *green circles* highlight tissue reservoirs for transposition flaps of nasal defects.

Three common transposition flaps are the rhombic (single-lobed), bilobed, and trilobed flaps (Fig. 39-17).¹⁸ The latter two flaps have a significant rotational component as well. Adding lobes to the flaps recruits tissue from reservoirs increasingly remote from the primary defect and displaces tension to more favorable vectors. Defects on the proximal nose and sidewall are immediately adjacent to the tissue reservoir, so the single lobe of the rhombic flap may be adequate (Fig. 39-18A). Defects on the supra-tip and proximal nasal tip may require a bilobed flap (Fig. 39-18B), and more distal defects may require a trilobed flap (Fig. 39-18C). In general, the angle between the defect, primary lobe, and secondary lobe dictates whether a trilobed flap is needed, as maintaining acute angles, ideally 45 degrees or less, results in tension-free flap motion.

Figure 39-18. Transposition flaps for nasal reconstruction. (A) Rhombic flap. (B) Bilobed flap. (C) Trilobed flap.

As opposed to sliding flaps, which have the greatest tension at the primary defect, transposition flaps displace tension to the ultimate donor site (i.e., secondary defect of a rhombic flap; tertiary defect of a bilobed flap; and quaternary defect of a trilobed flap). By transferring tension to the donor defects over the proximal and lateral nose, the transposition flap can be rotated to the primary defect under minimal tension.

Rhombic transposition flaps

Rhombic flaps are useful to reconstruct smaller defects of the proximal nose and sidewall by recruiting tissue from the nasal root, sidewall, and cheek (Fig. 39-19). The flap extends from the midline of the defect toward the desired tissue reservoir. For nasal defects, the open limb of the flap usually points laterally (i.e., the flap has a laterally based pedicle), which eases closure of the donor site and helps to push the flap toward the defect. The classic rhombic flap has a 60-degree angle at its apex, but lengthening the flap to create a more acute apical angle can facilitate closure and avoid a standing cone deformity at the donor site.

Figure 39-19. Rhombic (single-lobed) transposition flap. (A) A rhombic flap is designed to recruit from the tissue reservoir immediately adjacent to this small defect. Note that the open limb of the flap points laterally. Tissue is recruited from lateral to medial, which pushes the flap toward the primary defect. (B) The flap has been transposed into the primary defect, and the standing cone has been excised along the alar groove. (C,D) At short-term follow-up, the scar is inconspicuous from the lateral and frontal views.

To avoid secondary motion at the primary defect, the flap should have approximately the same surface area as the defect and extend perpendicularly

to the defect.¹⁸ The first key suture closes the secondary defect and bears the greatest amount of tension. The second key suture sets the flap into the primary defect and determines its arc of rotation as well as the position of the standing cone. As the arc of rotation increases, pivotal restraint effectively shortens the flap, making it more difficult for its distal edge to reach the defect, and the standing cone deformity may encroach on the flap pedicle. It is preferable to set the flap so that the standing cone deformity does not narrow the pedicle. Removing the standing cone is often reserved until the flap has been set in its ideal location.

The triangular shape of the distal flap does not correspond to typically circular defects. The surgeon can either trim the flap to match the defect or triangulate the defect to accommodate the flap. Since the distal flap has the most tenuous blood supply, it is usually preferable to trim the excess tissue of the flap to match the defect.

Bilobed flap

If a rhombic flap is not possible because tension on the skin immediately adjacent to the primary defect is excessive or causes anatomic distortion, the bilobed flap can reach donor sites more remote from the defect. The flap is most useful for defects of the nasal tip and supra-tip (Fig. 39-18B). Compared to the rhombic flap, the geometry and execution of the bilobed flap are more complex.¹⁸⁻²¹

Like the rhombic flap, the bilobed flap also rotates approximately 90 degrees (Fig. 39-20). However, the bilobed flap distributes the rotation between the two lobes, each rotating 45 degrees. The second lobe adds a Z-plasty component that helps push the flap toward the primary defect. The tension vector to close the donor site for the secondary lobe (i.e., the tertiary defect) should generally be horizontally oriented (parallel to the alar rim) in order to prevent free margin displacement.

Figure 39-20. Bilobed flap. (A) A laterally based bilobed flap is designed to repair this moderately sized defect of the nasal tip. Note the nearly vertical orientation of the secondary lobe on the nasal dorsum. (B) Immediate postoperative appearance demonstrates preserved position of the free margins of the tip and alae. (C) The nose has good contour and an inconspicuous scar at long-term follow-up.

The first key suture closes the tertiary defect. On the nose, the first suture pushes the flap toward the primary defect more effectively when the final, open limb is positioned laterally (i.e., a laterally based bilobed flap) versus medially (i.e., medially based bilobed flap). The second key suture sets the primary lobe into the defect. The exact position of this suture may vary or require adjustment to create tension vectors that avoid anatomic distortion, to align the standing cone, and to adjust the sizing of the primary lobe. It is often preferable to ensure that closure of the standing cone deformity preserves contour, before trimming excess tissue for a precise fit. The secondary lobe will generally have excess length and require trimming to match the secondary defect.

Trilobed flap

The trilobed flap has tissue mechanics similar to the bilobed flap with a few distinct advantages (Fig. 39-21). First, its third lobe allows the flap to reach tissue reservoirs increasingly remote from the primary defect, and it is particularly useful to reconstruct distal nasal defects. Second, the third lobe extends the arc of rotation to 120 to 150 degrees and may provide a more favorable tension vector to close the quaternary defect. Third, the additional lobe adds the benefit of another Z-plasty, which decreases the tension to transpose the flap, an important advantage when even mild tension at the distal nose can distort the free margins. Finally, the third lobe increases the

width of the flap pedicle. If the orientation of the standing cone would cut into the pedicle of a bilobed flap, the increased pedicle size of a trilobed flap may improve blood supply.²²

Figure 39-21. Trilobed flap. (A) A laterally based trilobed flap is designed to repair a Mohs defect of the lateral nasal tip. The third lobe was necessary to ensure a horizontal (i.e., parallel to the alar rim) tension vector at the quaternary defect. (B) The position of the alar margin is preserved immediately

postoperatively. (C,D) The nasal contour is preserved and the scar is inconspicuous at short-term follow-up.

Nasolabial transposition flap

The nasolabial transposition is a modified rhombic transposition useful to reconstruct defects of the alar groove and ala (Fig. 39-22).²³ The flap recruits tissue from the generous reservoir at the nasolabial fold. Since the alar groove and ala have scant fat, and since the skin is firmly adherent from the dermal insertions of the underlying muscles, this flap can appear too thick and pincushion without precise undermining plane and tacking sutures to recreate the alar groove.

Figure 39-22. Nasolabial transposition flap. (A,B) A nasolabial transposition flap is designed to repair a deep defect that spans the lateral alar groove. (C) Immediate postoperative appearance. The skin is tacked to the pyriform aperture to recreate the alar groove. (D,E) Contour is restored and the scar is minimally apparent at follow-up.

The medial arm of the flap extends from the lateral aspect of the nasal defect down along the nasolabial fold. The lateral arm of the defect extends along the cheek in a parallel line that gently tapers to join the nasolabial fold at its inferior aspect. The horizontal widths of the proximal flap and defect should be identical. The superior aspect of the cheek limb of the flap should remain a couple millimeters inferior to the origination point of the medial limb. This slight discrepancy is important to orient the primary tension vector in a superomedial vector that recruits skin from the mobile buccal cheek.

The flap is elevated to include only the subdermal fat. If it includes the nasolabial fat pad, the flap will have too much volume. The nasolabial fold and cheek are undermined in the same tissue plane.

The key suture closes the donor defect at the flap's origination point. If the wound is under high tension, tacking the cheek to the origin of the transverse nasalis along the pyriform aperture may be necessary to avoid lateral distraction of the nose. The distal portion of the flap is trimmed to match the size of the defect, and it is sutured to the primary defect. The alar groove has a deep concavity, and the flap will pincushion if the dead space is not closed. Tacking the base of the flap to the caudal margin of the transverse nasalis muscle is usually necessary to close dead space and restore contour of the concave alar groove. Transposition of the flap creates a standing cone along the nasal sidewall, which is removed taking care to preserve the flap pedicle.

Interpolation Flaps

Interpolation flaps transfer skin from remote reservoirs with a pedicle that bridges an isthmus of skin between the primary defect and the donor site. The flap pedicle remains intact until the blood vessels at the recipient site grow into and provide sufficient nourishment to the transferred skin. The ingrowth of new vessels is usually reliable after approximately 3 weeks, and the pedicle is divided during a second surgical procedure. Despite the disadvantage of more than one surgical stage, interpolation flaps are

indispensable to repair large nasal defects that exceed the limits of local flaps or skin grafting.

Two interpolation flaps are common for nasal reconstruction. The melolabial interpolation flap (MIF) (cheek-to-nose interpolation flap) recruits skin from the melolabial fold and derives its blood supply from muscle perforators arising from the angular artery. This flap is most useful for defects of the ala, lateral nasal tip, and columella. The paramedian forehead flap recruits skin from the forehead and has an axial blood supply from the supratrochlear artery (STA). As a result of its larger tissue reservoir and more robust blood supply, the paramedian forehead flap is a more versatile flap capable of reconstructing wounds at all nasal locations. For a detailed discussion of interpolation flaps, see [Chapter 26](#).

Melolabial interpolation flap

The MIF, also known as the cheek-to-nose interpolation flap, is a random-pattern flap based upon the muscular perforating arteries branching from the facial, superior labial, and angular arteries in the nasolabial fold area ([Fig. 39-23](#)).²⁴ The primary advantage of this two-staged flap is that it preserves the deep concavity of the alar-facial sulcus, the hairless apical triangle of the upper cutaneous lip, and the narrow isthmus between the melolabial fold and alar lobule. Authors have described multiple variants of the MIF, such as a banner-type flap,²⁵ and an interpolated paranasal flap from the hairless nasofacial sulcus.²⁶ The flap can be used to repair defects of the ala, nasal tip, and columella. This chapter will focus on the traditional design for alar defects ([Fig. 39-24](#)).^{27,28}

Figure 39-23. Trajectory of the facial artery and its perforators. An average of six perforating vessels from the facial artery pierce the overlying SMAS (retracted with forceps). The *black arrows* indicate the level of two of the perforating vessels.

Figure 39-24. Nasolabial interpolation flap and free cartilage graft. (A) A nasolabial interpolation flap is designed for this anterior alar defect. A medially based trilobed flap was also considered. (B) Intraoperative photo showing a free auricular cartilage graft bracing the alar margin. (C) Appearance immediately after interpolation of the flap. (D) Appearance after takedown and inset of the flap pedicle 3 weeks later. (E,F) Follow-up photos show a relatively inconspicuous scar and preservation of the alar groove.

Planning begins with the assessment of the defect. The alar lobule does not contain cartilage, so broad or deep alar defects jeopardize the position of the alar margin. Defects involving more than 50% of the distal alar lobule will usually require free cartilage grafts to brace the ala against scar contraction and to support the airway (Fig. 39-24B). The conchal bowl or the antihelix serve as excellent cartilage donor sites. These cartilage grafts stabilize and preserve the convex shape of the ala, optimizing both cosmesis and function. If the defect involves more than 50% of the alar surface, it may be expanded to include the entire alar subunit. The deep alar-facial sulcus at

the lateral ala is especially difficult to repair, so 1 to 2 mm of the native ala should be preserved in this region whenever possible.

A template is made to match the exact size of the final defect. The melolabial fold is carefully traced with a surgical marking pen (Fig. 39-24A). The template is removed from the nose and rotated approximately 110 to 120 degrees toward the midline and transferred to the melolabial fold. In general, the donor site is located at the midpoint of the melolabial fold between imaginary horizontal lines drawn laterally from the alar sill and labial commissure. Even in men, this location usually does not contain significant terminal hair that would be transplanted to the ala. A rolled gauze may be used to simulate the rotation of the flap and confirm adequate length.

The superior margin of the template will lie directly against the melolabial fold and the anterior margin of the template will be the most inferior portion on the cheek. After ensuring proper orientation, the margins of the template are traced with a surgical marking pen. The fusiform design of the MIF can be completed by drawing the anticipated Burow's triangles inferiorly along the melolabial fold and superiorly toward the nasofacial sulcus. To avoid standing cone deformities, the triangles should be drawn with sufficient length that the angles at the apices of the fusiform design are 30 degrees or less.

The templated portion of the flap is elevated at the junction of the subdermal fat and the nasolabial fat pad. Inclusion of the nasolabial fat pad within the templated portion of the flap will result in excessive thickness and bulky contour. Once the distal 80% to 90% of the templated portion of the flap has been dissected in this superficial plane, the dissection transitions to a plane in the deeper fat, with great care to preserve the perforators. The base of the proximal flap should be at least a finger width in breadth directly over the paranasal perforators just lateral to the ala. This most proximal dissection is performed with blunt scissor tips held parallel to long axis of the flap, spread about 3 to 4 mm apart and strummed or "pawed" with a gentle forward pressing motion. One can feel the plane separating freely. This dissection technique very effectively separates the fibrous septae necessary to loosen the flap while preserving the vessels. The same undermining technique is used to free up the flap at the superior margin and lateral margins, although there are more adherent fibrous connections along the alar crease junction and isthmus that often need some sharp dissection in the immediate subdermal plane above the muscle. Dissection continues until

the flap freely rotates toward the defect without tension or torque. The donor site is closed in a layered fashion to simulate the melolabial fold. The inferior standing cone is excised and discarded.

The margins of the nasal defect are undermined immediately above the lower lateral cartilage or immediately superficial to the vestibular mucosa on the alar lobule. If necessary, a free auricular cartilage graft is sutured to the vestibular lining, and may be tucked into the undermined areas. The flap is transferred to the nose and sutured under minimal tension with a layered closure, except at the alar rim, where only a simple layer of cutaneous sutures is necessary (Fig. 39-24C). Eversion should be avoided along the alar groove.

Three to four weeks later, the pedicle is divided. The base of the flap pedicle is excised as a fusiform ellipse along the superior nasolabial fold and may extend to the nasofacial sulcus. The donor site is repaired with standard layered closure.

The proximal aspect of the flap must be inset at the alar base and lateral alar groove. The proximal flap is elevated from the vestibular lining or free cartilage graft, and the proximal edges of the nasal defect are freshened, and all fibrotic and granulation tissues are excised. The subcutaneous fat and fibrotic tissue are thinned from the base of the flap to match the thickness of the ala. The flap is sutured into the alar crease with simple or layered closure, taking care to avoid eversion and simulate the normal concavity of the alar groove (Fig. 39-24D).

Paramedian forehead flap

The paramedian forehead flap has an axial blood supply based on the STA, though forehead flaps do not need to contain the STA for survival (Fig. 39-25). Planning begins with careful assessment of the defect. Modifying the depth and breadth of the defect can improve contour or help to camouflage scars within cosmetic subunit junction lines. The surgeon must weigh the benefits of defect extension against the risks of airway compromise and added donor site morbidity. Increasing the defect size may make donor site closure more difficult. It also may increase the pedicle length and the likelihood that the donor site will involve hair-bearing scalp. If the defect has missing cartilage, free cartilage grafting may be necessary to restore nasal contour and projection and to stabilize the airway. Full-thickness nasal defects present the greatest challenge, as they require repair of mucosa,

cartilage, and skin. Such defects are most common on the ala and soft triangle and may require a three-staged, rather than a two-staged, forehead flap.^{29,30}

Figure 39-25. Two-staged paramedian forehead flap. (A) A paramedian forehead flap is designed for this large nasal defect. The pedicle is based around the Doppler-identified path of the supratrochlear artery. (B) The flap template is undersized on the proximal nose to avoid a bulky contour. (C) Appearance 3 weeks after the flap inset. The patient is ready for takedown and inset of the flap pedicle. (D) Appearance immediately after a second-stage takedown and inset. Note that the flap has the desired contour. (E) The nasal scar is inconspicuous at follow-up and contour is restored. The patient declined serial excision of the inverted scar on the tight forehead.

Once the final nasal defect has been created, the surgeon must make a template to size the flap. An oversized template will result in a bulky flap. An undersized template will increase tension at the primary wound, potentially distorting the free margins or compressing the distal cartilages. For precise sizing of the template, it is helpful to mold a flexible material,

such as a nonstick gauze or aluminum foil of a suture package, to conform to the exact contours of the defect.

The template is then transferred to the forehead. Determining the side on which to base the flap depends primarily on defect location. For laterally based wounds of the ala, distal sidewall, or hemi-tip, the ipsilateral forehead is usually ideal. Ipsilateral flaps require less length to reach the wound and are therefore less likely to extend into scalp hair. For laterally based wounds of the medial canthus and proximal nasal sidewall, contralateral flaps have less torque and still reach the defect without difficulty. Midline nasal wounds can use either side as the donor site.

After determining the preferred side, the surgeon maps the path of the STA, upon which the flap pedicle will be centered. The most prominent glabellar frown line corresponds to the junction of the medial corrugator and procerus muscles, and can be accentuated by pushing the medial brows inferomedially toward the midline.³¹ The STA is located anywhere from this glabellar frown line to 6 mm laterally.³¹ The path of the STA can be traced with a Doppler probe to identify rare anatomic variations that will not be detected by topographic mapping.

Once the STA is mapped, the surgeon transfers the template to the forehead. To ensure proper orientation, the template is placed on the nasal wound, then rotated 180 degrees toward the side on which the flap will be based. The template is placed in line with the STA so that the portion corresponding to the distal wound lies just inferior to the hairline. If more length is required and the surgeon wishes to avoid transferring scalp hair to the nose, the pedicle can be diverted to the contralateral forehead. Even without an axial blood supply, the distal flap will still have sufficient perfusion via the subdermal plexus.³²

To ensure that the flap will reach the nasal defect, a gauze pad can be stretched from the most proximal part of the pedicle to the distal part of the template near the hairline, and rotation of the flap can be simulated with the gauze. After assuring adequate length, the surgeon can finalize the design. The template is situated at its precise forehead location, and its border outlined, with the proximal pedicle centered on the STA. A pedicle base width of 1.1 to 1.4 cm safely includes the STA and minimizes the increased torque seen with a broad pedicle. The flap's templated portion is usually

wider than its base. To optimize its blood supply, the narrow portion should widen progressively until it meets the templated portion.

The flap is elevated. For two-stage flaps, the thickness of the flap ideally matches the depth of the defect, since aggressive thinning during pedicle division and inset may compromise blood supply. If the incision extends through frontalis or galea before reaching the proximal 10% to 20% of the templated portion of the flap, the flap will usually have excessive volume.

Once the templated portion of the flap is elevated, the dissection proceeds through the frontalis and continues in the plane of the loose connective tissue. A scalpel or blunt-tipped scissors dissect the tissue away from muscle with minimal effort. As the dissection approaches the brow, the surgeon will see yellow fat deep to the corrugator muscle. Cotton-tipped applicators can be used to push away the corrugator muscle fibers without causing bleeding of the superior orbital plexus. Vessels deep to the corrugator are left intact to minimize venous congestion, but can be precisely electrocauterized if necessary. Flap length is assessed by rotating the flap toward the midline, and the dissection stops when it reaches the nasal wound without tension.

If the template has been sized precisely and the flap and defect thickness match, inset should be straightforward. For a two-staged flap, cartilage grafts should be placed prior to inset. The main objectives during flap inset are to align the templated portion with its corresponding nasal defect site. Undermining the defect margins prior to inset may help prevent pincushioning. The distal flap is anchored to the nasal wound; suturing proceeds proximally along its lateral aspects.

The forehead donor site is undermined in the loose connective tissue and closed in three layers, with buried sutures for the frontalis and dermis, and superficial cutaneous sutures if needed. Any area too tight to close primarily maybe left to granulate. Intact frontalis muscle and loose connective tissue under the templated portion of the flap can speed healing. The shiny scar from a wound left to heal by second intention will often be aesthetically acceptable. Efforts to close the forehead site with rotation flaps or grafts lengthen the procedure, increase discomfort, and provide few long-term cosmetic benefits. If the forehead scar is unsatisfactory, serial excisions spaced several months apart will usually permit direct closure.

After the flap is inset and the forehead donor site is closed, the pedicle is inspected for any bleeding. Indirect hemostasis closes larger vessels and precise direct hemostasis controls bleeding of smaller vessels in the

subdermal and dermal plexuses. Failure to control bleeding of the pedicle diverts blood from the distal flap. After careful hemostasis, a hemostatic bandage (e.g., Surgicel®, Puracol®) wrapped gently around the pedicle controls minor oozing. The patient may be prescribed analgesics and antiemetics, which are especially important in patients with tension at the forehead donor site. Postoperative discomfort typically abates after 24 hours.

Three to 4 weeks later, the flap is fully integrated with the nasal blood supply, and the STA is no longer needed for its survival. The patient returns for a second procedure to divide the pedicle and inset the flap. The pedicle is incised. The edges of the proximal nasal defect are freshened and all fibrosis and granulation tissue are removed from the base of the wound. Likewise, the fibrosis and granulation tissue are removed from the undersurface of the proximal flap and the flap is trimmed to match the precise dimensions of the nasal defect. The proximal flap is sutured in a layered fashion.

Attention is then turned to inset the pedicle at the medial brow. If the pedicle base was carried through the brow to increase flap reach, the hairs may have been pulled inferiorly and medially. To maintain symmetry, the surgeon may want to realign them by trimming the flap pedicle in the shape of an upside-down “V.” If inseting the hairs is not necessary, it may be possible to excise the base of the pedicle and repair the wound with a linear closure. Carefully placed dermal sutures promote eversion and minimize pincushioning.

CONCLUSIONS

Key principles of anatomy guide assessment of nasal defects and planning of the reconstruction. When possible, nasal defects can be closed with linear repairs, though given the complex topography of the nose and the multiple free margins that are prone to distortion, even relatively small defects may benefit from flap closures. The complexity of a closure, and the projected intensity of postoperative care, should be considered carefully, particularly in patients with multiple comorbidities. The range of options for surgical reconstruction should be addressed with the patient prior to surgical intervention.

CHAPTER 40 Reconstruction of the Lips

J. Michael Wentzell
Glenn D. Goldman

SUMMARY

- Lip reconstruction has significant aesthetic and functional implications.
- Attention to cosmetic subunits, as well as important landmarks such as the white line, is of paramount importance.
- Linear and wedge repairs are generally most straightforward, though larger defects benefit from a variety of flap approaches.

Beginner Tips

- Small defects on the upper and lower cutaneous lip may be repaired in a linear fashion; aim to orient closures along existing creases if possible.
- Advancement flaps are frequently performed for mid-size defects on the upper cutaneous lip; incise parallel to and 1 mm from the vermillion border for ideal camouflage.

Expert Tips

- While island pedicle flaps have a reputation for undesirable scarring, this can be largely obviated by judicious undermining and meticulous suturing.
- If the nasolabial fold is blunted, Z-plasty can be considered approximately 6 months postoperatively.
- Partial closures may be useful in select patients, particularly those reluctant to undergo larger procedures.

Don't Forget!

- Z-plasty may be useful for the management of trigone deformities.
- Mucosal advancement flaps should be performed with a minimal number of buried sutures.

Pitfalls and Cautions

- The white line in younger patients is very pronounced; deviation of less than 1 mm may still yield a cosmetically obvious mismatch.
- Larger lip reconstructions, such as the Karapandzic flap, must be performed precisely to avoid disastrous outcomes.

Patient Education Points

- Always gauge a patient's willingness to undergo and recover from an extensive procedure *before* it is initiated.
- Some patients may prefer a small partial closure to a more involved and much larger flap.

- Patients should be warned against opening their mouths wide, eating fruit such as apples, and other activities that stretch the orbicularis oris in the immediate postoperative period.

Billing Pearls

- Most flaps on the lips are coded with 14060 or 14061, and these codes include the excisional component; it is not appropriate to bill both an excision and a flap repair code simultaneously, except for Mohs excision codes.
- When coding a flap, graft, or linear repair, medical necessity is the ultimate arbiter of appropriateness.

CHAPTER 40 Reconstruction of the Lips

INTRODUCTION

The lips and perioral region represent a critical region both aesthetically and functionally. They are central to facial expression, are sensory organs for food and personal contact, and provide oral competence at rest and during mastication. The lips also have rich vasculature and sensory innervation.

The perioral region is bounded by the nasolabial folds laterally and superiorly, and by the mental crease of the chin inferiorly. The lips are suspended only by muscles and the fibrous tissues of the modiolus at each oral commissure. Therefore, the lips and the oral commissures represent mobile free margins. Reconstruction of the perioral region requires meticulous planning to direct tension in appropriate vectors. Retraction of the upper lip margin creates the appearance of a hair lip. Midline retraction may simulate a cleft lip repair. Distortion of the lateral oral commissure can lead either to drooling or a permanent sneer. Depression and/or eversion of the lower lip may lead to a loss of oral competence. [Table 40-1](#) reviews many of the complications unique to lip reconstruction ([Figs. 40-1 through 40-20](#)).

Figure 40-1. (A) Wound involving entire apical triangle. The subalar upper lip is an especially effective donor site to reconstruct the apical triangle. (B) Flap in position. (C) Appearance at suture removal. Apical triangle preserved.

Figure 40-2. Aligning the wet line after the white line (vermillion border) can result in a fat lip deformity.

Figure 40-3. (A) Wet line step-off when vermilion border is aligned as first step in reconstruction. (B) Aligning the wet line (instead of the vermilion border) results in a step-off at the vermilion border. (C) A sliding Z-plasty restores vermilion alignment while the wet line prioritized closure averts a fat lip deformity. (Reproduced with permission from Wentzell JM1, Lund JJ: Z-plasty innovations in vertical lip reconstructions, *Dermatol Surg.* 2011 Nov;37(11):1646–1662).

Figure 40-4. (A) In a white line prioritized lip alignment, a wet line step-off and trigone deformity can occur under common conditions. A fat lip deformity can occur with correction of the wet line step-off. In a wet line prioritized alignment, a sliding Z-plasty corrects the white line misalignment. In addition, tension vectors c' , d' , and e' are reduced relative to tension vectors c , d , and e , reducing the source of the trigone deformity. (B) A Z-plasty will “slide” one side relative to the other side if the central limb is not the same length as the side limbs. In practice, the surgeon may elect a short central arm or a long

central arm, but the Z-plasty configuration must change to achieve the same correction, depending on whether the central limb is short or long.

Figure 40-5. (A) Rotation flap creating trigone deformity of the vermillion border. (B) Trigone deformities and fat lip deformities are evident at suture removal and do not improve with time. (Reproduced with permission from Wentzell JM1, Lund JJ: Z-plasty innovations in vertical lip reconstructions, *Dermatol Surg.* 2011 Nov;37(11):1646–1662).

Figure 40-6. (A) When the wound is sutured, tension vectors create forces that pull the vermillion border into a triangular deformity. (B) Z-plasty designed to correct the incipient trigone deformity at the initial closure. (C) With Z-plasty execution, the vermillion border is compelled to follow a smoothly continuous curve.

Figure 40-7. (A) Large upper lip defect. (B) and (C) Vertical revision outlined and initiated. (D) In this case, approximation of wet line does not result in vertical misalignment of vermillion border because the lip's cross-sectional arc of curvature is the same medially and laterally. A sliding Z-plasty is not necessary. However, wound closure completion at this point would result in a “corner” or trigone deformity at the border. (E) and (F) A traditional Z-plasty compels the vermillion border to follow a smoothly continuous line. (G) Long-term result without trigone deformity. (Reproduced with permission from Wentzell JM1, Lund JJ: Z-plasty innovations in vertical lip reconstructions, *Dermatol Surg.* 2011 Nov;37(11):1646–1662).

Figure 40-8. Exaggerated creasing of right upper lip scar due to repeated muscular contraction. (Reproduced with permission from Wentzell JM1, Lund JJ: Z-plasty innovations in vertical lip reconstructions, *Dermatol Surg.* 2011 Nov;37(11):1646–1662).

Figure 40-9. (A) Vague vermilion border zone. (B) Defect with Z-plasty outlined. (C) Z-plasty executed. *Arrows* demonstrate misalignment of vermilion border. (D) Final outcome. Misaligned border is imperceptible. Horizontal limb of Z-plasty acts as a reinforcing strut to counter contractile forces that cause exaggerated creasing. (Reproduced with permission from Wentzell JM1, Lund JJ: Z-plasty innovations in vertical lip reconstructions, *Dermatol Surg.* 2011 Nov;37(11):1646–1662).

Figure 40-10. (A) Vermillion border defect. (B) Partial closure just deflecting superior and inferior wound margins to counteract wound contraction forces. (C) Long-term result. (D) Cutaneous lip defect. Complete 3:1 closure would result in inferior dog ear necessitating wound extension through wet line. (E) Wound closed just to the point where superior and inferior wound margin deflection will neutralize opposing contractile forces while the wound heals. (F) Short-term result.

Figure 40-14. (A) Larger cancer excision site compared to Figure 40-13. (B) Appropriately sized V–Y island pedicle marked for Z-plasty. (C) Executed Z-plasty on lower horizontal line will camouflage scar. Two or more Z-plasties can be deployed as necessary.

Figure 40-15. Fish-mouth deformities arise due to the same force vectors as trigone deformities. Scar contracture often contributes.

Figure 40-16. (A) Broad defect into muscularis. (B) Defect appearance after wedge excision. (C) Approximation with incipient fish-mouth deformity. (D) Z-plasty corrects fish-mouth deformity. (E) Final horizontal arm of Z-plasty in labial-mental sulcus.

Figure 40-17. (A) Large, deep upper lip defect. (B) Design of combined rotation flap and wedge. Either closure alone would cause significant distortion or possible microstomia. (C) Final closure. (D) Long-term result.

Figure 40-18. (A) Broad defect of lateral lip in youthful face equal to 60% of total width from commissure to mid-upper lip. (B) Medial wedge combined with (C) small lateral graft derived from hair-bearing submental neck crease. (D) Short-term result amenable to dermabrasion. A single flap or graft or wedge would cause much greater distortion and possible microstomia.

Figure 40-19. (A) Defects extending to muscularis. (B) Final outcome of second intention healing. (C) Two weeks after extensive excision to muscularis. (D) Final outcome with second intention healing. In many cases, second intention healing provides a superior result even for excisions of the entire lower lip, and even those involving muscularis or extending to the cutaneous lip.

Figure 40-20. (A) Rotation flap designed with lateral vermillion wedge to prevent hooding. (B) Flap in position. (C) Z-plasty designed. (D) Flap fully executed. (E) Long-term result. No lateral hooding is seen.

Table 40-1. Common Complications in Lip Reconstruction: Causes and Prevention

Complication	Common Cause	Prevention
Asymmetrical “smile lines”	Narrowing or elimination of the apical triangle during reconstruction.	Maintain the width of the apical triangle by deploying flaps or grafts (Fig. 40-1A–C).
Fat lip deformity (Fig. 40-2)	Aligning vermillion border to close a wound on a lip with broader vermillion medially than laterally (Fig. 40-3A–C).	Align the wet line first and utilize a sliding Z-plasty to align any noticeable vermillion border mismatch (Fig. 40-4A and B).
Trigone deformity (Fig. 40-5A and B)	Arises because of the physics of counterbalancing tension vectors during wound closure (Fig. 40-6A–C).	Utilize Z-plasty to decrease radially directed tension (Fig. 40-7A–G).
Exaggerated deepening of radial scar (Fig. 40-8)	Repeated contraction of orbicularis oris.	Place a small Z-plasty in the vertical (radial) closure line of linear closure or flap (Fig. 40-9A–D).
Persistent “dog ears”	Stopping a vertical (radial) linear closure on a convex surface.	(a) Lengthen wound closure on the cutaneous lip to more than the standard 3:1 ratio. (b) Lengthen the closure of a wound completely through the wet line, creating a mini wedge. (c) Utilize partial closures (Figs. 40-10A–F, 40-11A–D, and 40-12A–E).
Noticeable horizontal scar line on a V–Y island closure (Fig. 40-13A and B)	Horizontal line runs counter to radial expression lines.	Place one or more Z-plasties in lower horizontal line of closure (Fig. 40-14A–C).
Fish-mouth deformity (Fig. 40-15)	This is the midline manifestation of the trigone deformity coupled with scar contracture.	Deploy Z-plasty into vertical repair (Fig. 40-16A–E).
Microstomia	Primary approximation of large lip wounds.	Abbe flaps, transposition flaps, and grafts. Focus on combinations of closures (Figs. 40-17A–D and 40-18A–D).
Foreshortening (narrowing) of lower lip vermillion	Mucosal advancement flaps.	Second intention healing (Fig. 40-19A–D).
Appearance of a cleft lip repair	Loss of philtrum. Linear repairs of philtral defects decrease distance between philtral ridges.	Utilize flaps or grafts that maintain distance between philtral ridges.
Failure of wet line seal	Depression or misalignment of wet line. Often caused by mucosal advancement flaps or retracting trigone forces.	Utilize secondary intention healing. Prioritize wet line reapproximation rather than vermillion reapproximation. Utilize traditional or sliding Z-plasties.
Nonkeratinizing vermillion	Repairs that displace wet mucosa anterior to the wet line.	Where practical, do not displace wet mucosa anterior to wet line. Use second intention and primary closures maintaining dry mucosa on lip.
“Hooding” of the oral commissure	Upper lip rotation or advancement flaps that impinge on commissure.	Trim flap adequately. Where possible, stop the vermillion border incision medial to commissure. Remove wedge from vermillion as necessary (Fig. 40-20A–E).

BIOANATOMY AND BIOMECHANICS

Perceptually, the upper lip is composed of multiple cosmetic subunits (Fig. 40-21).¹ The central philtral subunit is bounded on either side by the philtral ridges, the medial borders of the lateral subunits. The lateral subunits of the upper lip are bounded inferiorly by the vermillion, medially by the philtral ridges, superiorly by the bases of the alae and columella, and laterally by the nasolabial fold. The apical triangle, sometimes called the isthmus, is the small triangular extension of the lip which lies lateral to the ala and medial to the superior most nasolabial fold. While small in size, it provides a

recognizable delineation between the lip, nose, and cheek; it should be maintained as an aesthetic marker whenever feasible.

Figure 40-21. Lip subunits: The upper lip is divided into a philtral subunit and two lateral subunits. The lateral subunits each contain an apical or “sacred” triangle lateral to the nasal ala. Maintaining the integrity of the philtrum, apical triangle, and nasolabial folds are goals of upper lip reconstruction.

The inner surface of the lip is the oral mucosa. The wet mucosa becomes vermillion as it exits the oral aperture and forms the red lip. External to the wet line, the vermillion surface represents “dry mucosa.” The keratinizing dry mucosa differs structurally from nonkeratinizing wet mucosa. For this reason, skin grafts of wet mucosa onto the dry mucosa of the vermillion do not mature into dry mucosa. Utilizing wet mucosa to repair the vermillion surface external to the wet line often yields suboptimal results.

Beneath the mucosa is a submucosal layer rich in minor salivary glands. The vermillion itself lies directly on a circumoral band of orbicularis oris and the underlying musculature has rich vascular supply. This leads to the red color of the lips. The structural bulk of the lip is composed of the orbicularis

oris, which forms circumferential rings and gives the lips their shape, definition, and function.

The facial nerve provides motor innervation for the perioral musculature via its zygomatic, buccal, marginal mandibular, and cervical branches. These nerves are highly anastomosed and deeply seated. Therefore, neural injury leading to a functional impairment of perioral function is rare, with the one exception being damage to the marginal mandibular nerve as it passes along the mandible. The infraorbital nerve provides sensory function to the upper lip, and the mental nerve innervates the lower lip (Fig. 40-22).

Figure 40-22. Sensory innervation of the perioral region. The upper lip is innervated by the infraorbital nerve and the lower lip is innervated by the mental nerve. The lateral commissures receive sensory input from the cervical nerves and require separate local anesthetic.

Anesthesia of the lip is readily achieved by nerve block (see [Chapter 12](#)). The upper and lower lip each receive a large branch from the facial artery as it ascends toward the alar crease (Fig. 40-23). The arteries run in the submucosa and become tortuous with age. They give off many perforators and branches, anastomosing at the midline.

Figure 40-23. Vasculature of the perioral region. The upper and lower lips are richly supplied by large labial branches of the facial artery. The labial branches are tortuous with age and run on the submucosal side of the orbicularis oris.

The junction of the vermillion and the cutaneous lip is a bright, clear line in younger adults. A thin, elevated, well-defined band of pale glabrous skin (the white line) marks the border with the cutaneous lip. With age, this definition fades progressively until the vermillion border is no longer a line but a vaguely defined zone up to 4 mm wide where vermillion blends in a continuum with the cutaneous lip. The reconstructive surgeon must remain keenly aware of the width of this vermillion/cutaneous transition. If the patient has a white line, the repair must be meticulous, reapproximating the white line on apposing wound margins. If the vermillion/cutaneous transition is a wider “zone” of transition, the vermillion alignment is less critical. The observing eye will not notice the repair scar as long as the vermillion “border” on either side of the repair falls within the vaguely defined “zone.”

The youthful lip often has a prominent philtrum, and the vermillion border of the upper lip is crisp and voluminous. The nasolabial folds are not well

developed in youth. Instead they are soft, minimally depressed inclinations. With age, the upper lip flattens, the philtrum is less prominent, and the vermillion border is less defined. The nasolabial folds become fixed and sharply recessed, clearly defining the lateral margin of the upper lip (Fig. 40-24).

Figure 40-24. Variation in the lip with age. (A) Lips of a 25-year-old woman. The vermillion is full and sharply defined. The philtrum is elevated and distinct. Repairs may be noticeable, even if the scar line is fine and sharp. (B) Lips of a 45-year-old woman. The vermillion has lost some volume. The philtrum has lost some elevation and is less distinct. A few vertical lines have formed. (C) Lips of a 65-year-old woman. Volume loss and loss of the philtrum are more advanced and vertical rhytides are more pronounced. Repairs are often less visible.

There is tremendous variation in the shape of the perioral region, and this has an impact on reconstruction (Fig. 40-25). Some individuals have a small oral opening, while others have a broad, wide mouth. The upper lip may be high and arched, or low and flat. The distance from the columella to the vermillion varies dramatically from person to person, as does the span from commissure to commissure. While most younger individuals have a prominent philtrum, in some it is minimal even in youth. In some older

individuals there is no residual philtrum at all. Such variation impacts operative reconstruction, as what may be a simple repair in some individuals can be a challenge in others.

Figure 40-25. Variations in size and configuration of the mouth/lips. (A) Small oral aperture. Loss of any substantial component of the oral diameter may lead to relative microstomia. (B) A broad upper and lower lip make reconstruction easier in the event of a sizeable defect.

This chapter focuses on the aesthetic and functional repair of modest wounds of the upper and lower lip. A storied history of reconstruction of the lip for large wounds dates to the late 1500s and involves some of the historically great reconstructive surgeons. In recent decades, dermatologic surgeons have greatly expanded the available repertoire of sophisticated reconstructions. While generally beyond the scope of this text, the artistry and geometry involved in the history of extensive wound lip reconstruction are well worth examining.²

REPAIR-RELATED DEFORMITIES

Any surgical wound of the lip can be repaired successfully in a variety of ways. By and large, the art of reconstructive surgery is the art of minimizing deformities. During reconstructive planning and execution, the foremost question in the surgeon's mind must be, "How do I best serve this patient's goals?" If those goals are best served by a reconstructive effort, the next most important question to ask oneself is, "How do I minimize noticeable deformity?" and not "How do I close this wound with XYZ closure?"

To develop the "deformity avoidance" mindset, the reconstructive surgeon must have a thorough understanding of how deformities arise during and after

reconstruction. A mental catalog of possible deformities and their causes is more important to the reconstructive surgeon than the mental catalog of the repairs in the surgeon's toolbox. [Table 40-1](#) reviews some of the more salient deformities that the reconstructive surgeon should minimize or avoid altogether.

[Figure 40-6](#) demonstrates why a trigone deformity develops. In an upper lip wound, for example, if the medial vermillion border is oriented horizontally, but the slope of the lateral border is oblique, the original forces on the lip change when the surgeon approximates wound margins. A new upward force and a new medial force (defined by a single composite tension vector) now act on the wound's lateral vermillion border. There is a concomitant two-component (lateral/downward) composite force now applied to the medial vermillion border.

When two forces act on a single point, that point will move along the net vector. Physics dictates that the movement continues until either (a) the original tension vectors are aligned at 180 degrees (i.e., the slope of the vermillion border is perfectly flat) or (b) the net tension vector along which the point moves is ultimately opposed by an equal and opposite tension vector.

In practice, "b" is the only scenario that happens if one sutures two sides of a wound whose opposing medial and lateral vermillion borders are not horizontally co-linear. In this case, a "corner" will form along the vermillion border at the physical point where there is an equalization of the three tension vectors. If the angle of that "corner" is broad, the effect is minimally noticeable. As forces increase, however, the angle becomes more acute; there will be a progressively more noticeable "corner" at the vermillion border.

This is termed a "trigone deformity." It does not occur in suturing the wound in a thin, flat lip, as there is no upward or downward force on the rejoiner vermillion border.

A trigone deformity is an inevitable outcome of the physics of tissue movement in a lip with vermillion border of changing slope. It can accompany a fat lip deformity, though this does not occur consistently. While the trigone deformity relates to the changing slope of the vermillion border, the fat lip deformity relates to the changing cross-sectional arc of curvature.

UPPER LIP

Lateral subunits

The lateral subunit of the upper lip is bounded by the nasolabial fold, the alar crease, the philtrum, and the vermillion border. Nonmelanoma skin cancer of the upper lip is very common. Hence, repair of the upper lip lateral subunit is a frequently required reconstruction.

Partial repairs

The figures and discussions included in [Table 40-1](#) demonstrate that partial repairs of the lip can offer acceptable results with minimum morbidity and reduced cost ([Fig. 40-10](#)). This is true even when the defect straddles the vermillion border. Patient selection, of course, is of critical importance. Repairs can often be executed without significant extension or conversion to a fusiform shape, and no attempt to excise incipient standing cutaneous cones. Partial repairs can dramatically foreshorten the length of the repair, averting standing cutaneous cone formation over the perioral convexities.

The key to partial repairs is to tighten the sutures (buried and/or surface, at the surgeon's discretion) just to the point where incipient standing cutaneous cone formation begins. With experience, the surgeon can know exactly how much cone formation will be exactly countered by the healing-process wound contraction. A flat scar of absolutely minimum length will result. In most cases, the surgeon should move up one suture diameter and leave sutures in place for roughly an extra week to prevent respreading of the wound with suture removal. In other words, as a rough approximation, if a linear closure at the site typically requires 6-0 suture removed at 10 days, the partial repair utilizes 5-0 suture for 2½ weeks. As the wound contracts, the suture typically becomes lax and irrelevant. Of course, one may elect no surface suture at all, tensioning the wound with only deep sutures.

Linear repairs

Small and modest wounds of the mid-upper lateral subunit may be repaired linearly ([Fig. 40-26](#)). Vertical lines on the lip are common with age. With

proper execution, such repairs can be highly aesthetic and lead to minimal or no functional impairment. The most appropriate wounds for a linear repair are those which lie above the vermillion border and whose vertical axis is longer than the horizontal axis. Linear repairs on the lip do not need to be exactly vertical. They generally should parallel the philtral columns medially but remain perpendicular to the vermillion border as it arcs slightly with its lateral procession. Linear repairs on the lip must be long and should be carried right through the vermillion border.³ In most cases, the outermost orbicularis band should be transected and excised as a “mini wedge,” without which a standing pucker of lip will often exist (Figs. 40-27 and 40-28). Dog ears on the lip do not recede, and therefore the repair must be long enough and deep enough (just above orbicularis) to ensure that it lies flat at the moment of closure. In addition, the sharper the defining line between the vermillion and cutaneous lip, the more meticulous must be the alignment of apposing wound margins. In patients with a well-defined white line, even mismatch of a millimeter or less of vertical height will create a visible deformity and ruin what may otherwise be a nearly invisible repair. Patients with a vaguely demarcated vermillion border “zone” require less meticulous vermillion border alignment.

Figure 40-26. For modest wounds of the lip a vertical linear closure is an excellent repair. (A) A vertically oriented wound on the lip and a linear repair design for closure. (B) The closure is long and passes right through the vermilion border in order to avoid a pucker at the inferior margin. (C) Final result at 1 year with aesthetic repair.

Figure 40-27. Fullness and puckering of the vermilion following a vertical linear repair. This is particularly problematic when smiling as it shows against the teeth. This can be avoided in most cases with proper planning and technique. (A) Immediate linear repair on the lip showing fullness and “bulldozing” of the upper lip vermilion. This can be avoided by removing the distal orbicularis oris band. (B) Photo at 6 months demonstrating resolution of most puckering, but still some fullness of the lip.

Figure 40-28. A slightly larger wound on the upper lip is repaired with a linear closure in which the distal/surface band of orbicularis oris is removed. (A) Operative wound. (B) The repair is performed in the potential space above the orbicularis musculature and is extended right through the vermillion border. The distal/surface band of orbicularis is excised and repaired as a “mini wedge.” (C) Immediate closure without pucker formation. (D) Aesthetic closure healing at 3 months.

Lip wedge

Wounds involving the vermillion border of the lateral upper lip are common. Many such defects can be repaired with a full-thickness or modified full-thickness wedge reconstruction (Fig. 40-29).⁴ As originally defined, the wedge is a full-thickness V-shaped transmural repair. The operative wound edges are squared off and a full-thickness V-shaped “pie” of tissue is excised up to the gingival sulcus. The labial artery is either ligated or electrocoagulated, and the repair is then closed in a multilayer fashion. The mucosa is first closed with an absorbable suture such as plain gut. The muscle is then reapproximated with an absorbable buried suture, the dermis is separately repaired and then the epidermis and vermillion mucosa are reapproximated.

Figure 40-29. A modest wound of the lateral upper lip and vermilion is repaired with a wedge. (A) Operative wound and planned wedge. (B) A full-thickness excision has been accomplished. (C) The mucosa has been repaired. (D) The orbicularis oris has been reapproximated. (E) Repair at completion with careful matching of the vermilion border. (F) Repair at 6 months.

As with the simple partial-thickness closures, in patients with a sharply defined white line it is imperative to carefully match the vermilion borders. If the defect is broad and the lip narrow, a wedge will lead to a mismatch between the smaller lateral cutaneous lip and vermilion and the taller more substantive medial remnant. The result will be a functional lip but a visible mismatch. This may be a tolerable deformity but should be considered if the

patient has high cosmetic expectations. A sliding Z-plasty technique can effectively overcome this mismatch.⁵

A wedge reconstruction of any defect that encompasses more than one-quarter of the upper lip has the potential to cause microstomia; for larger wounds, combination repairs, rotational flaps, and lip-sharing procedures may be preferred. The advantage of a lip wedge is that it is a relatively nonmorbidity repair with a low risk of complications. As with partial-thickness repairs, wedges need not be entirely vertical but should align with radial relaxed skin tension lines (RSTLs) that are typically perpendicular to the vermillion border.

Any vertical line scar on the upper or lower lip can demonstrate exaggerated creasing with time, due to repeated contraction of the orbicularis oris muscle. A Z-plasty (traditional or sliding) incorporated into the vertical incision line of a linear repair, wedge, or flap acts as a strut that resists this creasing. When the Z-plasty is executed, the depth of incision for the arms of the Z-plasty is typically down to muscularis. In practice, the final horizontal central limb of the Z-plasty is not noticeable.⁵

A modification of the lip wedge avoids extending the repair all the way to the gingival sulcus and preserves some muscle (Fig. 40-30).⁶ In the modified technique, the external repair is extended the full vertical height of the lip, but the internal extent is only about 50% of the height of the lip. The distal band of orbicularis is completely severed, as is the labial artery, but the larger, deeper major circumoral band of orbicularis is preserved. This repair is less extensive than the full-thickness wedge and may preserve a more normal circumoral muscle tone in the postoperative period. From an aesthetic standpoint there seems to be little difference from the standard lip wedge.

Figure 40-30. A modified wedge repair is performed as a partial-thickness closure without extension all the way to the gingival sulcus. (A) Operative wound and planned repair. (B) The wedge has been accomplished by excising the entire vermilion and all of the distal bands of the orbicularis oris. The labial artery has been ligated and transected. The upper bands of the orbicularis are preserved, and the wound edges are undermined free of the muscle. (C) The repair is closed by repairing the mucosa and the distal orbicularis band. (D) Immediate result without lip distortion. (E) Aesthetic repair at 6 months.

Advancement

Many moderate to large cutaneous wounds of the upper lip lateral subunit can be suitably repaired with unilateral advancement flaps (Figs. 40-31 to 40-

33).^{3,7-9} These large repairs use laxity from the medial cheek to allow for a nearly tension-free closure, thus avoiding philtral and vermillion distortion.

Figure 40-31. Figure and photos demonstrating a cheek advancement for a sizeable operative wound on the medial aspect of the lateral subunit. (A) Operative wound. A linear repair or wedge would distort the lip and displace the philtrum. A graft would be highly unaesthetic. (B) A large advancement flap is designed with crescentic standing tissue cones to be removed around the ala and lateral to the oral commissure. (C) The flap is elevated above orbicularis. This is an area with rich vasculature, and precise hemostasis is essential. (D) Immediate closure. The most challenging aspect of this repair is judging the effect of the advancement on the position of the lateral upper lip/vermillion. (E) Repair at 6

months demonstrating normal form and function and excellent cosmesis. (Used with permission from Dr. Todd Holmes).

Figure 40-32. In a modification of the prior repair, a large upper lip wound is repaired with a cheek advancement and a separate vermilion advancement (A) A large operative wound might be repaired with a lip wedge, but the patient is a tuba player and wishes to maintain his embouchure. (B) Advancement is designed to tap into laxity of the medial cheek. A crescentic standing tissue cone is delineated around the alar margin. (C) The flap is elevated out to and beneath the nasolabial fold. (D) The repair at completion. The vermilion has been undermined and advanced/rotated separately. (E) Repair at 9 months demonstrating mild asymmetry.

Figure 40-33. A large defect of the left upper lip is repaired with a cheek advancement and a mucosal island pedicle flap. (A) Operative wound encompasses much of the lateral subunit and includes a mucosal defect. (B) The mucosal wound has been repaired with a mucosal island flap. (C) Advancement planned. (D) The flap has been advanced into place. (E) Final result at 1 year demonstrates normal lip contour. There was some tension on this repair, and the scars are visible and hypopigmented.

For defects near the vermillion, a standing tissue cone is removed superiorly and a broad flap is advanced from the lateral lip and medial most cheek. The design includes an inferior base which parallels the vermillion

border just a millimeter above it and extends lateral to the oral commissure, where a standing tissue cone is removed as the flap advances. The flap is elevated in the plane just above the orbicularis oris. When the nasofacial sulcus is reached, a reservoir of freely mobile tissue is tapped. The flap is thus freed of essentially all pivotal restraint. The flap should not be bulky and, in general, does not include any muscle fibers. The pedicle is from the superolateral aspect of the flap. Freed from all lip restraints, the flap may be advanced without distortion of the lateral vermillion. It is essential that all tension be directed in a horizontal plane. Substantial attention to detail is required to ensure appropriate positioning of the lateral lip to avoid any tension on or depression of the ipsilateral vermillion. If in doubt, it is better to slightly depress the oral commissure rather than elevate it, as slight depression is easier to correct in follow-up. In most cases, the strong musculature of the perioral region will reestablish the position of the mouth within several months such that prolonged positional distortion is rare, though every effort should be made to have a tension-free closure.

For defects closer to the nose, or for very large defects of the upper lip, a modified advancement flap includes an arciform standing tissue cone that extends up and around the nasal ala and alar crease. By extending the repair superiorly and around the ala, the entire medial cheek can be mobilized. Even extensive lip wounds can be suitably repaired in this manner. When the surgeon elevates such flaps, it is important to avoid transferring a deep, bulky flap onto the upper lip. The base of the flap is broad, and the blood supply is reliable. As such, a relatively thin flap may be advanced with confidence. Even appropriately thin upper lip advancements may pincushion for a period of several months, though as a rule they will eventuate in an aesthetic repair. Thicker flaps without adequate undermining, and those with improper sizing, will remain bulky and unsightly appearing as a finger of tissue seemingly placed onto the lip, and in these cases revision is needed.

All upper lip advancements have an impact on the nasolabial fold, and asymmetry is a consequence. The aesthetic compromise of an absent nasolabial fold is usually offset by repair of a more important location, namely the upper lip, but this expectation should be discussed with the patient prior to repair. If needed, the nasolabial fold may be recreated at a later date.

Rotation

Rotation flaps are niche repairs on the upper lip, but can prove exceptionally valuable in the appropriate situation (Fig. 40-34).¹⁰ Defects amenable to rotation are small to moderate wounds of the lateral subunit in the perialar region. Such wounds are often repaired with island pedicle flaps (see below). If the wound is repaired linearly, the superior standing tissue cone removal compromises the apical triangle of the lip. The ideal candidate is a patient with a relatively high and broad upper lip and a prominent arciform nasolabial fold. The repair is designed by dropping a standing tissue cone from the wound to the vermillion border. The arc of rotation extends along the nasolabial fold. The flap is elevated above muscle and all the way to the vermillion border. In this rotation, tension is directed in large part along the primary tension vector, and the rotation is used to eliminate tissue redundancy. The rotated arc can generally be sewn out along the nasolabial fold without removal of a dog ear. It is important only to utilize this repair when the wound is relatively small in relation to the size of the lateral subunit. If there is too much rotational torque on the flap, the lateral vermillion can be elevated, thus resulting in a sneer appearance.

Figure 40-34. Rotation flap for a wound of the apical triangle region. (A) Operative wound and planned repair. The crescent of the repair extends down the nasolabial fold. (B) The flap is incised. (C) The flap is elevated above orbicularis. (D) Flap at suturing preserves the apical triangle and minimally resets the nasolabial fold. (Used with permission from Dr. Todd Holmes).

Island pedicle flaps

Island pedicle flaps are excellent repairs for defects of the lateral upper lip and apical triangle (Fig. 40-35).^{11–13} Even substantial operative wounds can be reliably closed with an island flap based on the perforators of the orbicularis oris and surrounding perioral vascular plexus. Island pedicle flaps are most valuable when one or more limbs of the flap can be hidden along a pre-existing line. If all three lines of the flap are visible “floating” on the lateral upper lip, the result is not aesthetic. Modest wounds of the apical triangle are particularly well suited to the island pedicle flap, as the outer limb of the flap is hidden within the nasolabial fold. In some cases it is useful to enlarge the operative wound to encompass the entire apical triangle region. Such repairs should be designed with adequate width to allow for

closure of the operative wound without tension along a secondary vector. The length of the flap is tailored to allow for the advancement needed for the primary motion to close the operative wound. In general a longer flap is easier to elevate, advance, and suture. A Z-plasty modification of the lower horizontal line can enhance results (Fig. 40-14A–C).¹⁴

Figure 40-35. Classical repair of an upper lip wound with an island pedicle flap. (A) Wound of the left upper lip near the apical triangle. (B) Island flap design. The upper outer limb of the flap approximates the nasolabial fold. (C). The repair is advanced into place. The pedicle for this flap may be a deep muscular pedicle or a superolateral fatty pedicle. (D) Final result at 6 months.

Labial island pedicle flaps are incised just to the underlying orbicularis oris. The surrounding tissues should be undermined just above muscle. The advancing margin of the flap must be undermined to avoid a “bulldozing” phenomenon and the posterior, lateral, and inferior restraints must be meticulously freed. In order to achieve an aesthetic repair the flap should advance under little tension. A small but well-mobilized pedicle is favored over a bulky, adherent one. Slightly inseting the island and undermining the remaining lip widely can minimize pincushioning. Even when performed

elegantly, some trap-door effect is common for these repairs, though this will reproducibly diminish with time. When the operative wound includes an undermined region of the nose, the advancing margin of the pedicle may be de-epithelialized and advanced under the remnant ala (Fig. 40-36).

Figure 40-36. An island flap may be used to recreate a base for an undermined alar defect. (A) A large defect involves the apical triangle, much of the upper lip lateral subunit, and a small portion of cheek. A cheek advancement will close the defect of the nasofacial sulcus and an island flap is designed to repair the lip wound and stabilize the ala. (B) The cheek has been advanced medially and the island has been advanced underneath the ala to support it. The leading edge of the island has been de-epithelialized. (C) Repair at 1 year. (D) There is some asymmetry, as the apical triangle has been ablated and the nasolabial fold has been moved medially. This could be repaired with a Z-plasty if the patient so desired.

Large, even extensive operative wounds of the upper lip can be repaired with an island pedicle flap that straddles the nasolabial fold and extends out onto the cheek, lateral and inferior to the oral commissure (Fig. 40-37). This type of island flap is based not on the orbicularis oris, but on the richly vascularized adipose tissue of the medial cheek. Wounds of up to 3 cm can be closed readily with broad, large island flaps. In such cases, the flap is

undermined entirely off the orbicularis oris. The lateral pedicle is preserved, and the trailing tension vector is completely severed. The skin of the cheek is dissected free of the pedicle at a shallower plane. This is a robust flap, as it pulls the facial artery medially with it as the wound is repaired. As noted above, peripheral undermining and a slight inset of the flap at suturing can diminish pincushioning in the postoperative period.

Figure 40-37. Very large wounds of the upper lip may be repaired with island flaps. (A) Large wound of the lateral upper lip. (B) Repair with a large cheek island flap based on a fatty pedicle.

Nasolabial flaps
